Kaposi's sarcoma–associated herpesvirus (KSHV) is the eighth human herpesvirus and is formally known as human herpesvirus 8 (HHV8). KSHV is the most recently identified herpesvirus among the human herpesviruses. Chang et al¹²⁵ first identified the virus from acquired immunodeficiency syndrome (AIDS)-associated Kaposi's sarcoma (KS) tissues. KSHV has been classified as a member of the lymphotropic gammaherpesvirus subfamily. In this chapter, we review the discovery of KSHV, epidemiologic evidence linking the virus to multiple human cancers, and the clinical description of these viral cancers. We will also discuss the detailed latent and lytic life cycles of the virus and the contribution of viral proteins to disease pathogenesis.

KAPOSI'S SARCOMA–ASSOCIATED HERPESVIRUS: DISCOVERY AND CLASSIFICATION

KS was first described by a Hungarian dermatologist named Moritz Kaposi in the late 19th century as *Idiopathisches multiples Pigmentsarkom der Haut*.³²⁰ Classically considered an indolent disease of older men, the disease was later found to be

more common in the Mediterranean region as well as in parts of Africa.^{18,284} In several regions of Africa, KS afflicts children as well as adults. Prior to the emergence of human immunodeficiency virus (HIV) infection in the human population, KS was considered a rare neoplasm in the United States and Western Europe. However, with the advent of pandemic HIV in the early 1980s, KS emerged as the most common AIDS-defining cancer. The linkage between KS and HIV infection first prompted speculation that HIV was the etiologic agent of KS; however, this was disregarded in light of many epidemiologic studies. First, classical KS occurred before the AIDS epidemic and was originally seen in HIV-negative individuals. Second, even among HIV-positive subjects, certain groups are distinctly different in their risk for KS development. KS was more widespread among patients who acquired HIV via sexual routes (e.g., men who have sex with men), compared to individuals who acquired HIV parenterally (e.g., children and hemophiliacs).⁴⁶ These data suggested that KS might be acquired by a sexually transmitted pathogen other than HIV, which initiated a hunt for the etiological agent in question. In 1994, Chang et al¹²⁵ identified KSHV genomic DNA in KS lesions but not in normal tissue using representational difference analysis. By 1996, the Chang and Moore group (and others) had sequenced and cloned the entire viral genome.^{496,497,501,571}

It is now generally accepted that there are four classes of KS, only one of which is strongly linked to HIV infection: classic KS, endemic or African KS, iatrogenic KS associated with immunosuppressive therapies in transplant patients, and epidemic or AIDS-related KS. These classes of KS are described in further detail later in the chapter.

Although KSHV was first identified in an endothelial tumor, it was later found to be associated with lymphoproliferative disorders, which were greatly increased in AIDS patients. The KSHV genome is consistently present in two B-cell lymphoproliferative diseases.^{107,625} One such disease is primary effusion lymphoma (PEL), which is an expansion of B cells predominantly in serosal cavities such as the pericardium, pleura, and peritoneum, although infiltration of solid organs does occur. B cells in PEL are clonal in origin, as discovered by analysis of immunoglobulin rearrangements.^{247,338} Every PEL cell harbors KSHV DNA in the form of a circular episome, usually in multiple copies. Most PEL also harbor Epstein-Barr virus (EBV); however, KSHV is the defining pathogen for a diagnosis of PEL.

PEL can be established in culture relatively easily^{58,110,575} and form tumors in immunodeficient mice.^{58,99,533,631} PEL cell lines were the first system where KSHV replication could be induced *in vitro*,⁵⁶⁴ and they have yielded latent and lytic antigens for serologic test development.

Another B-cell disorder associated with KSHV infection is multicentric Castleman's disease (MCD). MCD is a rare, polyclonal,¹⁸⁸ lymphoproliferative disease that can develop in both HIV-negative and HIV-positive individuals. There are two histologic forms of Castleman's disease: a plasmablastic variant of MCD that is highly associated with KSHV and a hyaline variant that is more common in the unicentric form and not associated with KSHV infection. MCD is a systemic disease characterized by fever, weight loss, sweats, splenomegaly, and lymphadenopathy. MCD is an aggressive disorder that has a higher incidence in AIDS patients, where it is always associated with KSHV infection.⁶²⁵ The KSHV viral genome is present in the B cells of the mantle zones surrounding the germinal centers

(GCs). In a given germinal center, approximately 30% of B cells appear infected with virus.^{191,322,521} All KSHV-positive cells in MCD bear lambda light chains together with immunoglobulin M (IgM) heavy chains.¹⁸⁸ In HIV-negative individuals, only 50% of all MCD cases are linked to KSHV infection.^{522,625} Both PEL and MCD are described in greater detail later in the chapter.

The KSHV genomic sequence confirmed the classification of the virus as a member of the lymphotropic (or γ -) herpesviruses (Fig. 65.1). Lymphotropic herpesviruses can be further divided into two groups: the $\gamma 1$ or *lymphocryptoviruses* (which includes EBV and its simian relatives) and the $\gamma 2$ or *rhadinoviruses*. KSHV falls squarely into the latter category,⁴⁹⁷ which also includes the prototype primate virus, *Herpesvirus saimiri* (HVS). With the identification of additional primate rhadinoviruses, it is now evident that rhadinoviruses are represented by two different lineages, based on their biological properties and genomic organization: One lineage is represented by KSHV and a primate virus named *retroperitoneal fibromatosis herpesvirus* (RFHV), and a second group is represented by HVS and rhesus monkey rhadinovirus (RRV) (reviewed in 56).

VIRION STRUCTURE

Structurally similar to virions of other herpesviruses, KSHV virions exhibit an electron-dense nucleocapsid surrounded by a lipid bilayer envelope as visualized by electron microscopy. In between the capsid and envelope is a morphologically amorphous but highly organized proteinaceous layer called the *tegument*. The envelope is studded with viral glycoproteins—for example, glycoprotein gB is thought to engage cell surface receptors and participate directly in viral entry. The virion contains six other glycoproteins, including open reading frame (ORF) 22 (gH), ORF39 (gM), ORF47 (gL), ORF53 (gN), ORF68, and K8.1.⁷³⁸ Little is known regarding the architecture of the tegument. However, multiple proteins have been identified that localize to this region.^{40,738} KSHV tegument proteins share the common feature of being delivered to the target cell along with the genome upon primary infection and may thus contribute to early events in the replication cycle even before the synthesis of immediate-early (IE) proteins. This is also the case for the 11 viral messenger RNAs (mRNAs) that are incorporated in the tegument layer.³⁸ These virion mRNAs are derived from viral transcripts expressed in the prior lytic cycle and are incorporated into the tegument during the process of budding and envelopment. It is likely that one or more mRNAs are selectively incorporated into the virus particle.^{38,40} How such targeted recruitment might occur is unknown.

Several abundant host cytoplasmic proteins such as Hsp90 and pyruvate kinase are also found in the virions.⁴⁰ The KSHV capsid, like its HSV and HCMV counterparts, is icosahedral. A significant amount of work has been done to characterize the KSHV capsid structure in terms of its three-dimensional architecture and polypeptide composition.^{495,656,714} Cryo-electron microscopy reconstruction has revealed that the icosahedral capsid is symmetric ($T = 16$) with 20 triangular faces. The capsomers are composed of hexamers and pentamers of the major capsid protein (MCP; encoded by ORF25). Each capsid contains 150 hexons and 12 pentons, which are interconnected by 320 triplexes that are heterotrimer structures comprised of

FIGURE 65.1. A radial phylogenetic tree was constructed based on comparisons of the herpesviral DNA polymerase proteins from 12 primate herpesviruses showing the relationships between members of the alpha-, beta- and gamma-herpesvirus subfamilies. Kaposi's sarcoma-associated herpesvirus (KSHV) is the first human rhadinovirus, the prototype member of which is *Herpesvirus saimiri*. Rhesus lymphocryptovirus (rhLCV) is a simian herpesvirus that shows high sequence relatedness to Epstein-Barr virus. Rhesus monkey rhadinovirus and retroperitoneal fibromatosis herpesvirus are simian viruses that show high sequence relatedness to KSHV. The phylogenetic tree was constructed using the default parameters in the Multalin program with a Blosum62 matrix (<http://multalin.toulouse.inra.fr/multalin/>).

ORF62 (one copy) and ORF26 (two copies). The capsomeric hexons form the capsid edges and faces, whereas the pentons are located at each capsid vertex (Fig. 65.2). There are three types of capsid structures as identified by electron microscopy: an empty capsid shell (A capsid), a capsid containing scaffolding protein (B capsid), and a capsid encapsidating the viral genome (C capsid)^{173,174,495} (see Fig. 65.2). For the most part, the KSHV capsid

resembles the features of the more well-studied herpes simplex virus type 1 (HSV-1) capsid, with the exception that the KSHV hexons lack the presence of a VP26 subunit that is seen bound to the HSV-1 hexon subunits, and the KSHV triplexes appear smaller and less elongated than those of HSV-1.⁷¹⁴ The viral linear genomic DNA of 165 to 170 kb⁵⁶³ is located inside the capsid.

FIGURE 65.2. Kaposi's sarcoma-associated herpesvirus (KSHV) A-, B-, and C-capsid. **A:** Central slice of a tomogram showing the KSHV A-, B-, and C-capsid. **B:** Radially colored surface representation of an average KSHV capsid showing the characteristic herpesvirus capsomers, including an "umbilical" portal, 11 pentons, and 150 hexons. (From Deng B, O'Connor CM, Kedes DH, et al. Cryo-electron tomography of Kaposi's sarcoma-associated herpesvirus capsids reveals dynamic scaffolding structures essential to capsid assembly and maturation. *J Struct Biol* 2008;161(3):419–427, with permission.)

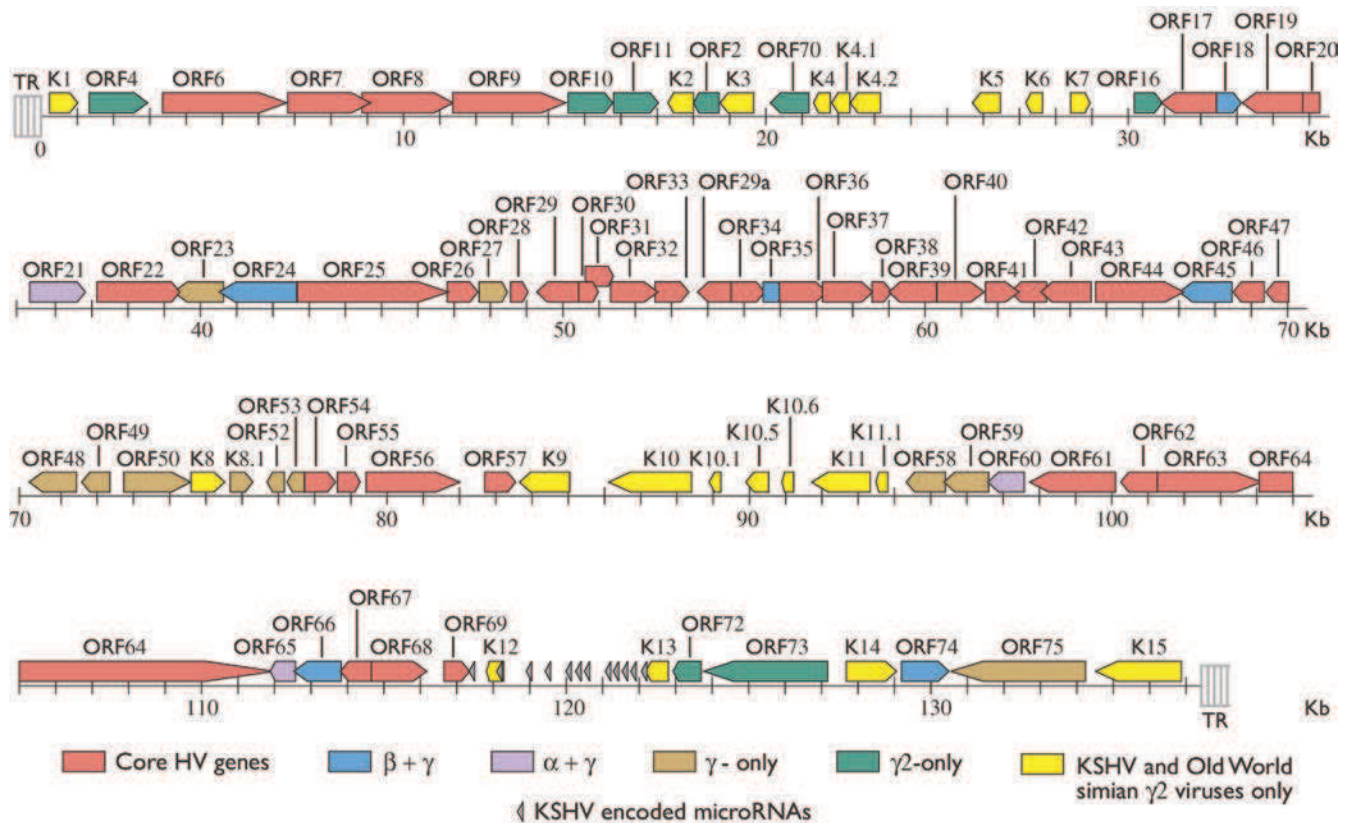

FIGURE 65.3. The Kaposi's sarcoma-associated herpesvirus (KSHV; human herpesvirus 8) genome map. Blocks of conserved genes between KSHV and related α , β , and γ herpesviruses are indicated by the same color. Arrows indicate open reading frames, with the direction of the arrow indicating the direction of translation.

KAPOSI'S SARCOMA-ASSOCIATED HERPESVIRUS GENOME: STRUCTURE AND ORGANIZATION

The KSHV genome is a double-stranded linear DNA that is 165 to 170 kb long.⁵⁷¹ The genome is comprised of a central unique region of approximately 145 kb encoding the viral genes.⁵⁷¹ The central region is flanked by highly GC-rich direct terminal repeats (TRs) (Fig. 65.3). Each TR unit is 85% GC rich and 801 bp long. Commonly, viral isolates contain 20 to 25 kb of TR DNA per genome; however, the exact number of TRs present at each terminus differs.³⁵⁸

Comparison of the KSHV genome sequence with other herpesviruses reveals blocks of highly conserved genes that are common to all herpesviruses (see Fig. 65.3). These are typically genes that encode for proteins involved in viral replication or proteins that encode for structural components of the virions. In addition, there is a group of genes that show homology to the gammaherpesvirus ($\gamma 1$ and $\gamma 2$) lineage and those that are only common to the $\gamma 2$ lineage. Finally, there is a group of genes that is only encoded by KSHV and its simian relatives but not present in other herpesviruses from nonprimate species—for example, KSHV viral interleukin 6 (vIL-6) and viral interferon regulatory factors (vIRFs) (see Fig. 65.3).

The KSHV ORFs are numbered in consecutive order from left (ORF1) to right (ORF75). KSHV contains numerous

ORFs that are not conserved in other herpesviruses, and these are interspersed among the conserved herpesvirus genes. The KSHV unique ORFs are given “K” designations—ORFs K1 through K15—numbered from left to right (see Fig. 65.3). Some of the K ORFs encode for more than one protein owing to alternative splicing and/or alternative translational initiation sites. Many of the K ORFs encode signaling molecules and proteins that are homologs of cellular genes (e.g., vIL-6 and vIRFs).^{496,571} The KSHV genome also encodes for many small noncoding RNAs, including a set of microRNAs (miRNAs)^{87,496,531,579} and polyadenylated nuclear RNA (PAN), a noncoding lytic 1.1-kb nuclear RNA.^{148,642,735,736}

Genetic Analysis of Kaposi's Sarcoma-Associated Herpesvirus

Construction of mutant viruses using homologous recombination has revolutionized the study of replication and pathogenesis of herpesviruses. Two methods have been used to generate recombinant KSHVs. In earlier work, PEL were transfected with a targeting vector encoding the viral gene of interest, disrupted by a green fluorescent protein (GFP) cassette and selectable marker. Stable GFP-positive cells were selected, followed by viral reactivation with 12-O-tetradecanoylphorbol-13-acetate (TPA) and supernatants were then tested for GFP transduction capacity.⁶⁷⁰ Zhou et al⁷³⁷ were the first to use BACmid technology to construct a KSHV BACmid. The entire KSHV

genome was cloned into a bacterial artificial chromosome (BAC), at a nonessential locus in the genome, with the BAC plasmid containing GFP and a selectable marker. The recombinant BAC was introduced into permissive cells, along with an expression vector for the key lytic protein, ORF50/replication and transcription activator (RTA); alternatively, the cells were treated with TPA, and reactivated supernatant virus harvested and amplified.⁷³⁷ Subsequently, this recombinant KSHV-BAC was then used for homologous recombination in *Escherichia coli* to make recombinant viruses. In principle, any nonessential gene can be rendered inactive using this protocol; for essential genes, *in trans* complementation is required to rescue the virus. Several groups have used BAC technology to make recombinant viruses. Recombinant viruses deleted for the following genes have already been constructed in the literature: gB, gpK8.1, ORF45, ORF50 (RTA), K8 (bZip), ORF56, ORF57, vFLIP, and ORF73 (latency-associated nuclear antigen [LANA]).^{170,272,323,346,373,429,688,721,725,741} In addition, replication-competent KSHV viruses with markers (GFP and RFP) to track latent (GFP) and lytic (RFP) infection have been constructed⁶⁷¹ and are highly beneficial for studies of viral infectivity.

VIRAL LIFE CYCLE

Viral Binding and Entry

KSHV is able to infect multiple cell types *in vitro* and *in vivo*. KSHV binds to and enters various human cell lines and primary cells in culture, including transformed B cells, primary B cells, 293 human embryonic kidney cells, THP-1 monocytic cells, myeloid and plasmacytoid dendritic cells (DCs), primary monocytes, human foreskin fibroblasts (HFFs), HeLa epithelial cells, and endothelial cells. KSHV can also infect monkey cells such as Vero and CV-1, hamster cells such as BHK-21 and CHO cells, and mouse cells *in vitro*.^{10,39,248,296,305,315,331,335,344,357,464,492,555,556,562,697,698}

KSHV encodes for multiple envelope glycoproteins; however, only three of these—gB, gH, and gL—are necessary to mediate membrane fusion.⁵²⁹ Attachment of the virion to the cell is thought to be mediated by several host receptor proteins as described later and highlighted in Figure 65.4.

Heparan Sulfate

Several glycoproteins encoded by KSHV have been shown to bind heparan sulfate present on the surface of the cell. These include KSHV gB, gH, ORF4, and gpK8.1A.^{12,52,270,490,676} The fact that the virus encodes four proteins that bind to heparan sulfate highlights the importance of this protein for attachment. Binding to heparan sulfate may contribute to efficiency of infection, because soluble heparan competes and hinders binding and impairs (but does not eliminate) infectivity. Thus, similar to HSV, the role of heparan sulfate binding helps to concentrate virus particles on the cell surface, thereby increasing their effective local concentration for interactions with cell surface receptors.

Integrins

Chandran and colleagues^{11,12,676} were the first to identify an integrin binding motif—the RGD (Arg-Gly-Asp)—motif, contained in the KSHV gB glycoprotein, and showed that it contributes to KSHV binding and entry. A twofold reduction in KSHV infection of endothelial and fibroblast cells was observed upon treatment with RGD peptides or antibodies

FIGURE 65.4. Kaposi's sarcoma–associated herpesvirus (KSHV) entry. Depicted are virion binding, attachment, and entry into the host cell. The different stages of KSHV entry are highlighted. Once the viral genome enters the nucleus, the decision to enter the latent or lytic phase of the life cycle is made.

against RGD-gB peptide.¹¹ Conversely, blocking of integrins using anti-integrin $\alpha3$ or $\beta1$ antibodies also prevented KSHV entry.¹¹ Subsequent studies have shown that $\alpha V\beta3$ and $\alpha V\beta5$ integrins also play roles in KSHV entry of adherent target cells.²³¹ Although anti-integrin antibodies reduced binding of KSHV to the cells, binding was not completely blocked suggesting that heparan sulfate is also required.

DC-SIGN

Dendritic cell–specific intercellular adhesion molecule 3 (ICAM-3)-grabbing nonintegrin (DC-SIGN; CD209) is expressed on activated B cells, DCs, and macrophages. KSHV is thought to bind DC-SIGN because KSHV infection can be blocked by an anti-DC-SIGN monoclonal antibody and soluble DC-SIGN.^{555,556} However, similar to the situation with the integrins mentioned earlier, these agents did not completely prevent KSHV binding to the cell, suggesting that additional binding partners may exist (e.g., heparan sulfate) (see Fig. 65.4).

The incomplete inhibition of viral entry by the integrin blocking antibodies supports the notion that although integrins play an important role in viral entry, other host proteins may also be involved in KSHV entry.

xCT

xCT is a 12-transmembrane glutamate/cysteine exchange transporter protein that has also been proposed to be a KSHV entry receptor.³¹⁶ xCT is part of the cell surface CD98 (4F2 antigen) complex containing a common glycosylated heavy chain and a group of 45-kDa light chains; the xCT molecule is one of the light chains. Expression of recombinant xCT protein in cells that are not permissive for infection restores permissivity to KSHV infection. Additionally, antibodies against xCT block infection.³¹⁶ Generally, xCT exists as a heterodimer with CD98, and this complex can associate with cell surface integrins (e.g., $\alpha 3 \beta 1$). Collectively, these studies demonstrate the interactions of KSHV with closely linked cellular receptor proteins (e.g., heparan sulfate, integrins, and xCT) in different cell types⁶⁶² (see Fig. 65.4). Additionally, there are likely to be many different entry pathways *in vivo*. Of note, the KSHV-encoded miRNAs were reported to up-regulate xCT expression in macrophages and endothelial cells through miR-K12-11 suppression of the transcriptional repressor BACH-1.^{546,614} The up-regulation of xCT by the KSHV miRNAs increased cell permissiveness for KSHV infection and protected infected cells from death induced by reactive nitrogen species.⁵⁴⁶ Most recently, the ephrin receptor tyrosine kinase A2 (EphA2) was shown to be a cellular receptor for KSHV.^{111a,270a}

Mechanisms of Viral Entry

Endocytosis is the predominant mode of KSHV entry *in vitro* for both adherent and nonadherent target cells.^{10,116,550,660} KSHV utilizes clathrin-mediated endocytosis and a low pH environment for its infectious entry into human fibroblast (HFF) cells.¹⁰ Electron microscopic observation of infected BJAB (KSHV- and EBV-negative B lymphoma) cells demonstrated virus entry via large, as yet uncharacterized, vesicles.¹² Studies using agents blocking acidification of endosomes suggested a low pH-dependent endocytic infectious entry pathway in human embryonic kidney epithelial²⁹³ cells. Studies also suggested endocytosis as the mode of KSHV entry in activated primary human B cells.⁵⁵⁵ KSHV induces actin reorganization and enters human microvascular dermal endothelial cells (HMVEC) and umbilical vein endothelial (HUVEC) cells via macropinocytosis.⁵⁵⁰ In these cells, KSHV also induced membrane blebbing⁶⁶⁰ in a c-Cbl-dependent manner. Unlike entry in endothelial cells, KSHV enters human monocytic THP-1 cells via clathrin/caveolin-mediated endocytosis.³³¹

Binding of the virus to the cell not only promotes viral entry but also triggers host cell signaling cascades that may modulate the cellular microenvironment to enhance virus infection. For example, binding of the cell surface integrins by KSHV triggers phosphorylation and activation of focal adhesion kinase (FAK). This activates several signaling molecules, including PI3K, Src, Rho guanosine triphosphatases (GTPases; RhoA, Rac, and Cdc42), and diaphanous 2 (Dia2). Downstream effector molecules of these signaling moieties are also consequently activated and include Akt, Ezrin, protein kinase C (PKC), MEK, extracellular signal-regulated kinase (ERK) 1/2, NF- κ B, and p38 mitogen-activating protein (MAP)

kinase.^{11,345,490,491,518,551,572,599,600,663,720,728} (A more detailed review of KSHV binding and triggering of signaling pathways can be found in reference 116.) Signal transduction does not need active viral replication, because ultraviolet (UV)-inactivated virions also elicit signaling, and signaling is inhibited by soluble $\alpha 3 \beta 1$ integrin peptides. Inhibitors of PI3K, PKC- ζ , MEK, and ERK can reduce KSHV infectivity.⁵⁹⁹ FAK-PI3K activation induced by KSHV binding also activates Rho GTPase and induces cytoskeletal rearrangements.^{599,600}

Following virion binding, cellular kinases are activated, leading to the recruitment of signaling molecules to the plasma membrane. These signaling proteins then rapidly translocate to clathrin, caveolae, and other vesicles.⁴⁵⁹ Src-mediated phosphorylation of clathrin induces the translocation of clathrin to the plasma membrane, where it interacts with AP2, Eps15, and dynamin.⁴⁵⁹ Src-initiated phosphorylation also triggers the assembly of the plasma membrane-associated Ras activation complex, leading to the downstream activation of Rho and Rab GTPases by Ras and PI3K. The Rho and Rab GTPases play critical roles in the formation and movement of endocytic vesicles.²⁷¹ These various KSHV-induced signaling events are summarized as follows:^{11,345,490,491,518,551,572,599,600,663,720,728}

1. KSHV binding to integrin triggers FAK activation, which appears to be critical for viral entry.^{345,600}
2. The activation of FAK and Pyk2 leads to the activation of the Src kinase family, which subsequently activates PI3K and Rho GTPases. Inhibitors of PI3K reduced viral entry, suggesting that PI3K's activation of Rac, Rho, Cdc42, and Rab5 GTPases are critical for viral entry, because they induce actin reorganization and provide the mechanical force required for endosome formation and trafficking. Induction of the downstream modulator Akt kinase early during the entry process may be beneficial for triggering a pro-survival environment in the infected cell.^{345,551,600}
3. PI3K and Rho GTPase activation leads to cytoskeletal rearrangements and the formation of structures such as lamellipodia (Rac), stress fibers (RhoA), and filopodia (Cdc42). This allows for microtubule acetylation and the thickening of microtubule bundle. This process is also essential for delivery of the viral capsids to the nuclear membrane via the microtubules.^{491,663}
4. KSHV also activates the ERK1/2 signaling pathway and the NF- κ B pathway. These pathways are thought to be important for viral gene expression.^{490,492,518,599,720}

The viral capsids traverse down the microtubules toward the nuclear membrane. Consistent with this description, microtubule-depolymerizing agents block infection.⁴⁹¹ It is thought that the capsid then injects the viral genomic DNA into the nucleus through the pore complex. Once the viral DNA enters the nucleus, the virus has a choice to enter either the lytic phase of its life cycle or the latent phase (see Fig. 65.4). During latency, the genome is circularized and subsequently is organized into chromatin through the assembly of cellular histones, thereby making it a suitable template for host RNA polymerase II transcription. During lytic replication, the virus is in a linear state amenable for viral DNA replication.

Innate Immune Response Following Viral Entry

Toll-like receptors (TLRs) are the first line of defense against invading pathogens. They recognize pathogen-associated

molecular patterns (PAMPs) present on invading pathogens and trigger signaling cascades, which lead to the activation of type I interferon (IFN), NF- κ B, and many other proinflammatory cytokines. Some TLRs are expressed on the cell surface (e.g., TLR2 and TLR4), whereas others are expressed in the endosome (e.g., TLRs 3, 7, 8, and 9).⁸ TLRs 3, 7, and 8 are activated by RNA. TLR3 recognizes both single-stranded RNA and double-stranded RNA, whereas TLR7 and TLR8 recognize single-stranded RNA. It is important to note that different cell types have distinct TLR expression profiles; hence, TLR recognition of an invading pathogen depends on the cell type being infected.

During infection of primary human monocytes, KSHV activates TLR3, resulting in the up-regulation of TLR3 expression (both mRNA and protein are increased) and its downstream mediators, including IFN- β 1 and the chemokine CXCL10 (also referred to as IP-10).⁶⁹⁷ As mentioned previously, KSHV is known to be endocytosed in monocytes, and during this process, it is possible that the viral RNA transcripts present in the tegument of the virus trigger TLR3 activation. In human plasmacytoid dendritic cells (pDCs), which are the chief IFN-producing cells in the body, KSHV infection triggers the activation of TLR9, a TLR whose agonist is CpG DNA.⁶⁹⁸ Thus, in pDCs, TLR9 is likely recognizing KSHV viral DNA. Unlike monocytes, human pDCs do not express TLR3 and only express TLR7 and TLR9. Finally, TLR4 appears to be important for recognition of KSHV in endothelial cells, as the virus can down-regulate TLR4 expression on endothelial cells.³⁵⁶ Both vIRF1 and viral G protein-coupled receptor (vGPCR) are involved in TLR4 down-regulation.³⁵⁶

TLRs also play a role in a very different context—for example, during reactivation from latency. Stimulation of TLR7/8 in KSHV latently infected PEL cells, either by synthesized agonist (poly-Uridine) or by infection with a biologically relevant pathogen (vesicular stomatitis virus—a known activator of TLR7 and -8), led to viral reactivation and progeny virion production.²⁵⁰ This represents a new role for TLR stimulation in the context of KSHV infection (which differs from the role that TLRs play during primary infection) and suggests a possible physiologic stimulus that can lead to viral reactivation *in vivo*.²⁵⁰

OVERVIEW OF THE LYTIC AND LATENT PHASES OF THE KAPOSI'S SARCOMA-ASSOCIATED HERPESVIRUS LIFE CYCLE

Following successful primary infection, KSHV can establish either a lytic or a latent state in the infected cell. Subsequent to initial viral infection, the host cell microenvironment is thought to govern the decision of which life cycle phase the virus enters. The default program appears to be latency. The kinetics of lytic versus latent gene expression during primary infection was examined in KSHV-infected endothelial cells and fibroblasts.³⁴⁴ ORF50/RTA levels were detected 2 hours postinfection but declined thereafter. Conversely, low levels of LANA were seen at first; however, expression increased substantially 48 to 72 hours postinfection. The latent genes were expressed continually, whereas lytic viral gene expression declined.³⁴⁴ Thus, concurrent expression of lytic and latent

genes occurs immediately following viral infection but only latent gene expression persists. It is thought that the minimal or marginal expression of lytic genes, many of which play key roles in immune evasion, cell proliferation, and prevention of apoptosis, could be necessary for the establishment and maintenance of latent infection *in vivo*.^{254,344}

Latency is the default pathway in most, if not all, experimental situations, and no virions are produced during this stage. During latency, viral gene expression is limited to only a subset of viral genes. The latent viral genome in the nucleus is replicated as an episome by host cellular DNA polymerase, and the replicated genomes are evenly distributed to the daughter cells. Although latently infected cells do not make virus, they maintain the viral genome and thus retain the potential for virus replication and virion production. Upon different exogenous stimuli, latently infected cells can undergo reactivation, a process that switches the virus from latency back into lytic replication mode. Physiologic stimuli during KSHV infection are not known; however, in tissue culture, several molecules can reactivate virus, including phorbol esters, histone deacetylase (HDAC) inhibitors (e.g., butyrate), TLR agonist stimulation, natural products from endemic regions, calcium ionophores, and IFN- γ .^{53,122,250,463,467,477,564,702,731,749} Additionally, cell differentiation has also been shown to induce KSHV lytic replication.^{311,597}

During lytic infection, the entire viral genome is expressed in a temporally regulated transcriptional cascade. Similar to other herpesviruses, the first set of genes that are expressed are known as the IE genes, which encode for transcriptional factors and regulatory proteins. The key lytic switch regulator is encoded by ORF50. ORF50 encodes for a protein referred to as RTA. Expression of RTA is sufficient to initiate the lytic replication cycle. The second temporal class of mRNAs encode for the delayed-early (DE) genes. The function of DE genes is to ready the cell for viral DNA replication and viral protein production. The DE genes encode for proteins (enzymes, co-factors) that are involved in viral DNA replication and proteins that affect nucleotide precursor pools and host transcription, as well as proteins involved in immune evasion. Once DE expression is under way, lytic cycle DNA replication commences in the nucleus. The objective of viral replication is to replicate the viral genomic DNA and produce many copies of the viral genomic DNA per cell. Subsequent to the onset of replication, the late (L) genes are synthesized. L genes are those that encode for viral structural proteins. These proteins are made after viral DNA replication because they are required in vast quantities. Late proteins are made after viral replication as they often need to be transcribed from genomic templates that have accumulated to a high enough copy number following viral genome replication.

After all three classes of IE, DE, and L genes are transcribed, virus assembly takes place in the nucleus. Newly replicated viral genomes are incorporated into newly synthesized viral capsids, which subsequently acquire their teguments by a poorly defined process. The capsids subsequently bud through host membranes in a series of steps to acquire a host-derived membranous envelope containing KSHV glycoproteins. Finally, viral progeny are released from the host cell. A more detailed view of KSHV latency and lytic life cycles is described later.

The transition to latency is not seamless. Following the first 12 hours postinfection, virus-infected cells display both lytic and latent gene expression.^{5,344} The lytic transcript profile is nontem-

poral in that different classes of IE, DE, and L genes are expressed simultaneously.^{5,344} It is possible that at least some of these lytic transcripts are delivered to the cell via the incoming virion tegument, which contains 11 viral lytic mRNAs that are assimilated into the virion during assembly.³⁸ Alternatively, some of these transcripts could represent genuine transcription using the host cell machinery. Some^{40,362} but not all⁷³⁸ studies have detected small amounts of the lytic switch protein ORF50/RTA in virions, which may contribute to this process. However, why the presence of RTA does not trigger the full lytic cascade is unknown and may depend on the host cell environment and the lack of sufficient amounts of cellular proteins required for lytic replication. Additionally, the level of viral DNA chromatinization also influences the ability of the virus to reactivate. Virion encapsidated viral genomes do not appear to harbor bound histones unlike the viral episomes found in latently infected cells.^{415,632} Several lytic transcripts represent inhibitors of apoptosis and viral mediators of immune evasion.³⁴⁴ At 24 hours postinfection, lytic gene expression declines, resulting in only latent gene transcription in the infected cell.

Approximately 24 to 48 hours postinfection, the classical latency program is established in nearly all infected cells, except for a small percentage (1%–3%) of cells that enter the lytic cycle. The frequency with which lytic infection ensues following *de novo* infection is related to the multiplicity of infection (MOI) and the cell type. For example, a high MOI in primary endothelial cells favors early progression into the lytic cycle. However, even under such circumstances, lytic replication tends to subside a few days postinfection, and the latency program dominates.

Our knowledge of the KSHV latent program comes from the study of PEL cell lines. These cells were originally isolated from PEL patients and subsequently propagated in cell culture.¹⁰⁷ PEL stably maintain latent KSHV genomes, and they express latent viral proteins in most of the cells. Although it is likely that latent gene expression in these cultured PEL cell lines is not representative of true latency *in vivo* per se, for the most part, mRNA transcripts identified in PEL are detected in other contexts (e.g., cell lines infected with KSHV *in vitro* as well as primary KS tumors).¹⁸¹

KSHV gene expression is complicated by the fact that a clear demarcation of latent versus lytic genes cannot always be made. For example, some genes are said to be expressed during latency (e.g., LANA), whereas other genes are expressed only during lytic replication (e.g., RTA/ORF50). However, although RTA is only expressed during the lytic cycle, LANA expression is observed during latency and lytic replication, suggesting a gray area in which some latent genes continue to be expressed at low levels during lytic replication, whereas other latent genes are expressed during latency and then highly up-regulated during lytic replication.

It is widely accepted that LANA, vFLIP, vCyclin, kaposins A, B, and C, and vIRF3 (aka LANA-2) are latent genes in PEL cells,^{179,567} as are the 12 pre-microRNAs (pre-miRNAs).^{87,579} However, there has been considerable debate about whether additional genes might also be expressed in latently infected cells, and several groups have shown that additional genes are expressed under some latent conditions. There is a class of genes that is expressed at low levels during latency but is highly up-regulated during lytic infection (e.g., vIL-6, K1)^{67,68,93,118,521,587,628,679} and K15 (Dr. Thomas Schulz, personal communication). Originally,

these genes were classified as purely lytic genes; however, more sensitive techniques indicate that these genes are also expressed at low levels under conditions in which there is no lytic gene expression.^{67,68,118,679} Additionally, the K1 promoter is active in epithelial, endothelial, and B cells in the absence of the lytic transactivator ORF50/RTA,^{67,68,118,679} lending credence to the fact that K1 is transcribed under latent conditions. A recent publication used tightly latent cell lines that displayed very low levels of spontaneous lytic reactivation to perform array-based transcript profiling and limiting dilution reverse transcription polymerase chain reaction (RT-PCR) in these cells. They found that both K1 and K2/vIL-6 genes were expressed under latent conditions.¹¹⁸ (This array was not able to analyze K15, which is another viral gene whose expression during latency has been controversial.) These results confirm earlier studies suggesting that K1 and vIL-6 could be viral latent genes.^{67,130,679} For K1, one compounding factor is that the protein is highly variable, thus antibodies against K1 from one strain may not readily recognize K1 from another strain, making protein expression analysis more difficult.^{67,130,679} It is also worth mentioning that in EBV, genes at the same genomic positions as K1 and K15 have been shown to be expressed during EBV types II and III latency and encode transforming abilities, raising the possibility of different latency patterns occurring during the KSHV viral life cycle.

In PEL, KSHV reactivation from latency is not 100%. During reactivation, low levels of latent gene expression can be detected in the background of lytic gene expression^{206,306,587} owing to the fact that it is usually not possible to reactivate all of the latent cells. Thus, there is always a background of latency. Finally, some viral gene products (e.g., vIRF3/LANA-2) are expressed in latent PEL but are not detected in latent KS spindle cells,⁵⁶⁷ whereas vIRF1 has been detected in latently infected KS cells but not in latently infected PEL.¹⁸¹ In EBV, at least three latent transcriptional programs have been described. Hence, the fact that KSHV also has a complex gene expression pattern should not be surprising.

In the following section, we first review the general patterns of latent and/or lytic transcription and then review the functions of these viral proteins.

Latent Phase Latent Transcripts

In PEL cells, the major latency transcript arises from a single genomic region, located between the K12 and Orf74 ORFs. At least two latent promoters are active, each of which initiate synthesis of a group of transcripts (Fig. 65.5). The first transcripts discovered originated from the LANA promoter, located just upstream of the LANA gene (ORF73).^{179,588,646} This promoter appears to be constitutively active. In transgenic mice, the LANA promoter drove LacZ expression mostly in B cells, although a few epithelial cells also demonstrated LANA expression.^{207,309} LANA promoter activity can be enhanced by exogenous expression of LANA, suggesting autoregulation of this transcript *in vivo*.³¹⁰ Additionally, there exists a second promoter element (just upstream of the latent LANA promoter) that up-regulates LANA transcription in the presence of increased RTA expression.^{362,447,630} There also exists a third latency promoter embedded within the LANA-vFLIP transcription unit that drives the vCyclin and vFLIP transcript, as well as the Kaposin transcript.^{382,526} All of these promoters also drive transcription of the viral miRNAs that are located in an

FIGURE 65.5. Map of known transcripts emanating from the main latency region of Kaposi's sarcoma-associated herpesvirus (KSHV). **A:** Top line shows map of the major genomic open reading frames (ORFs) (arrows), as well as the positions of most of the known microRNAs (miRNAs). Two major latency promoters exist: one 5' to ORF73 and the other just 5' to ORF72; each of these can generate the indicated spliced messenger RNA (mRNA) isoforms. Additionally, a lytic cycle promoter drives transcription of a 1.3-kb kaposin (K12) transcript. All mRNAs are polyadenylated at the indicated positions. (Modified from Yuan Y, Renne R. DNA tumor viruses. In: Damania B, Pipas J, eds. *Organization and Expression of the Kaposi's Sarcoma-associated Herpesvirus Genome*. New York: Springer Press; 2009:469–493.) **B:** A magnified view of the positions in the latency transcripts that encode the viral miRNAs.

intron obtained by read-through of the vFLIP-distal polyA-element and subsequent splicing.^{86,579}

This is a complex region of the viral genome because it has a nested arrangement of divergent promoters of latency genes (LANA, vCyclin, vFLIP, viral miRNAs) and lytic genes (vGPCR and K14). Thus, this region has a complex structure and intricate regulation so that lytic transcripts are suppressed during latent gene expression. A recent study showed that CTCF, a cellular protein that functions at chromatin boundaries, and cohesins, proteins that mediate sister chromatin cohesion, also bind to a specific site within the KSHV major latency control region.⁶³³ KSHV genes regulated by the CTCF-cohesin complex are under cell cycle control, and mutation of the CTCF binding sites abolished cell cycle-regulated transcription.³¹⁷ The cohesins interact with CTCF in mid-S phase

and repress CTCF-regulated genes in a cell cycle-dependent manner. Deletion of the CTCF-cohesin binding site in the KSHV genome caused an inhibition of cell growth as well as viral genome instability. Thus, CTCF and cohesins may play a critical role in regulating the cell cycle control of viral gene expression during latency.^{317,633}

The LANA promoter primarily drives transcription of three genes—ORF73 (LANA), ORF72 (vCyclin), and ORF71 (vFLIP), which utilizes both alternative splicing and internal translational initiation.¹⁷⁹ Figure 65.5 depicts the spliced mRNAs generated from this locus; all of these spliced transcripts are polyadenylated at a common site downstream of ORF71. The ORFs 73-72-71 tricistronic mRNA exists as an unspliced transcript, and another transcript with a small splice in its 5' untranslated region (UTR). An even more highly

expressed transcript is a spliced bicistronic transcript comprised of ORFs 72 and 71. This mRNA encodes both vCyclin (ORF72) and vFLIP (ORF71). vCyclin is translated by conventional cap-dependent initiation, whereas vFLIP (ORF71 or K13) translation is thought to occur through the use of an internal ribosome entry site (IRES) element located within the ORF of ORF72.^{50,255,411}

The second set of major latent transcripts in this region encodes for proteins from the kaposin locus (see Fig. 65.5). All mRNA transcripts originating from this locus are polyadenylated at a common site downstream of ORF K12. These transcripts include both ORF K12 and the upstream direct repeat (DR) sequences DR1 and DR2. When these mRNAs are translated, they generate kaposins A, B, and C proteins.⁵⁷³ Several latent promoters regulate the initiation of transcripts from this region. One transcript maps upstream of ORF72 and is spliced to a region just upstream of the direct repeats in latent PEL.^{86,382,526} Extensive transcript mapping has identified multiple spliced latent transcripts (all capable of expressing kaposins). Some of these transcripts originate from the LANA promoter through alternative splicing that removes ORFs 71 through 73^{86,526} (see Fig. 65.5). The spliced kaposin transcripts also encode for many of the viral miRNAs.^{86,87,257,531,579} Most of these miRNAs map to the region upstream of the kaposin DRs, which is essentially the intron of the latent kaposin pre-mRNAs. Other miRNAs map to the mature kaposin transcript (see Fig. 65.5). The miRNAs are derived by Drosha-mediated processing.

Finally, a separate promoter drives transcription of an unspliced mRNA (1.3 kb long) starting from a region upstream to the DR2 region⁵⁷³ (see Fig. 65.5). This mRNA transcript is made during lytic replication because its promoter contains RTA binding sites.¹²⁴ This results in the expression of high levels of kaposin proteins during lytic replication.⁶²⁹

Kaposi's Sarcoma–Associated Herpesvirus Latent Proteins

Latency-associated Nuclear Antigen

LANA, the product of ORF73,^{325,327,552} is a large and multifunctional protein that is present in the nucleus of latently infected cells. LANA exhibits characteristic punctate foci in the nucleus when examined by immunofluorescence and immunohistochemistry assays. LANA is highly immunogenic, and antibodies against LANA were the first utilized serologic markers of KSHV infection. LANA-specific CD8 T-cell responses have also been observed.³⁸¹ LANA has been detected in PEL and KS tumor cells *in vivo*, in B cells in MCD, and in every latent cell type infected *in vitro*.¹⁹¹ LANA has three major domains: an N-terminal domain involved in chromatin attachment and corepressor recruitment, a central region composed of highly acidic amino acid repeats, and a C-terminal basic region involved in DNA binding and oligomerization. LANA interacts with many viral and cellular proteins to exert its function. The binding sites for proteins that bind LANA is illustrated in Figure 65.6.

The best-characterized function of LANA is its involvement in the establishment and maintenance of the nuclear latent viral genome.^{28,152} The episomal viral genomes established in the nucleus during latency are replicated by the host DNA polymerase during cell proliferation in order to be

passed on to the daughter cells. LANA plays many roles in this latent replicative process. It directly binds DNA sequences within the TRs that contain the latent origin of replication^{29,153,229,230} and induces a bend.⁷¹⁰ The LANA–TR interaction initiates semiconservative replication by recruitment of the host DNA replication machinery to the viral episome.^{256,291,399} Each 801-bp-long TR contains a high- and a low-affinity LANA binding site (LBS1 and LBS2, respectively). LBS1 and LBS2 are separated by 22 nucleotides. There is a GC-rich replication element that lies upstream of LBS1 and LBS2. Deletion of this element hinders origin activity,^{293,665} suggesting that the replication element is the site for binding of cellular proteins involved in latent replication. In sum, LANA and the TR sequences recruit the host cell origin recognition complex (ORC) and mini-chromosome maintenance (MCM) proteins.^{399,632,664} LANA's C-terminal DNA binding domain binds the TRs at two sites which helps to recruit ORC and MCM.^{229,291,632,664} Although the C-terminal domain of LANA is sufficient for latent replication, the N-terminal chromosomal binding domain enhances latent replication, suggesting that replication and maintenance are interlinked.^{31,291}

TRs undergo reorganization in late G₁/S phase when replication licensing and initiation occur.⁶³² The structure-specific recognition protein 1 (SSRP1) and telomeric repeat binding factor 2 (TRF2) bind to LANA and the TR region²⁹² to facilitate viral episomal replication during latency.²⁹² The LANA–TR interactions are similar to the EBV EBNA-1–oriP complex, although LANA does not show significant sequence homology to EBNA-1, and the EBV oriP sequence is very different from the LANA binding elements of the TR. Yet, the LANA C-terminal DNA binding domain shows some similarity to EBNA-1 in terms of predicted secondary and tertiary structural motifs.²⁵⁶ Viral genomes are replicated once per cell cycle in synchrony with replication of the cellular genome.⁶⁶⁵

Semiconservative replication is not sufficient to explain the establishment of stable KSHV latency. A mechanism must exist in proliferating cells to ensure the proper segregation of replicated KSHV genomes to the daughter cells. Here, too, LANA plays a critical role. Transfected plasmids with KSHV TR elements joined to a drug-resistance selectable marker produced stable colonies at a higher frequency when LANA was present than in its absence.^{28,152} Such colonies display stably maintained circular genomes over subsequent generations, as is seen in PEL cultures. In interphase cells, viral genomes appear to be localized to LANA-containing dots or punctae. In mitotic cells, LANA and the viral episome co-localize to mitotic chromosomes. Thus, LANA can bind to mitotic chromosomes through its N-terminal domain.⁵³⁶ These data are suggestive of a model in which the N-terminus of LANA binds to the mitotic chromosome and tethers the viral genome (bound via its C-terminus) to this structure.^{32,347,718,729} This allows for the segregation of the tethered latent episomes to both daughter cells following mitosis. Tethering occurs through multiple protein–protein interactions, including binding to histones H2A–H2B, H1, centromeric protein F (CENP-F), budding uninhibited by benzimidazole 1 (Bub1), Brd4, and Brd2/RING3.^{32,152,347,451,539,672,718,729} Genetic evidence for this mechanism comes from the observation that a KSHV recombinant virus with a disrupted LANA gene does not generate a stable latent episome following primary infection.⁷²⁵

Bars indicate regions implicated in the indicated interactions or functions. **B:** Functional consequences of the interaction of LANA with other cellular and viral proteins. NLS, nuclear localization signal; P-rich, proline-rich region; Q-rich, glutamine rich region; L-zip, leucine zipper; DE, aspartic acid/glutamic acid rich repeats.

The plasmid replication and segregation functions of LANA are linked because point mutations in the N-terminus chromosome binding region of LANA are defective in the LANA plasmid replication assay.³⁹⁴ Additionally, the minimal LANA sequence required for plasmid DNA replication is comprised of both the N-terminal chromosome binding domain and the C-terminal oriP binding domain.³⁹⁷ Taken together, these findings give rise to the model that plasmid DNA replication occurs in association with host chromatin.

Viral episome maintenance may be more complex, however. In cells harboring the KSHV genome that do not make use of drug-resistance marker inserted in the viral genome, LANA, while necessary for plasmid maintenance, is not always sufficient. When LANA expression plasmids and the TRs are introduced into cells, the resulting episomes are very unstable

and rapidly lost during the process of cell division.²⁵⁴ This suggests that viral latency requires the *in vivo* environment.^{254,481} In certain cell lines, it has been shown that small subpopulations of cells do exhibit stable genomes and enter permanent latency similar to the case in PEL tumor cell lines.¹³⁴ In these cases, the viral genome undergoes epigenetic changes that enable it to be stably maintained in the cell.²⁵⁴

Curiously, the KSHV genome also contains a *cis*-acting DNA element within the long unique region that can initiate and support latent replication of plasmids lacking LANA binding sequences or a eukaryotic replication origin. The replication machinery proteins, ORC2 and MCM3, associate with this sequence and are required for replication of this element. Thus, KSHV can initiate latent replication of its genome in the absence of LANA or any other viral protein.⁶⁶⁶

Aside from its function in maintenance of the KSHV latent genome, LANA is also involved in the dysregulation of cell growth and survival. Transgenic mice expressing LANA from the latent promoter display splenic follicular hyperplasia and increased GC formation²⁰⁷ as well as an increased response to antigen stimulation.⁶⁰⁹ Some of the older animals developed B-cell lymphomas. The slow onset of lymphomagenesis suggests that LANA itself may not be sufficient for transformation and requires additional genetic changes once LANA drives the expansion of B cells, which is likely the result of LANA-mediated proliferation or LANA's ability to augment cell survival.⁶⁹¹

There have been many biochemical studies looking at LANA interactions with cellular proteins.^{135a,135b,323a} It has been found that LANA binds p53, and LANA-expressing cells display less activation of p53-dependent reporter genes and also are more resistant to p53-dependent apoptosis induced by irradiation and so forth.²¹⁵ At the same time, most PEL respond to p53 activating DNA damaging agents.⁵³⁰ LANA expression in endothelial cells extends their life span, although this does not lead to immortalization.⁶⁹¹

LANA can also bind the tumor suppressor Rb.⁵⁴⁹ This binding functionally inactivates Rb, resulting in increased E2F-dependent reporter gene activation in the presence of LANA. LANA can cooperate with Ras in 3T3 cell transformation, similar to the case with SV40 large T and small t antigens. However, in KSHV-infected tumors, this inactivation of Rb may be incomplete. For example, some PEL cell lines display a loss of p16^{INK4a}, a cdk inhibitor.⁵³⁸ Cdk inhibitor is a cellular cyclin D/cdk6 inhibitor, which in turn phosphorylates and thereby inactivates Rb. Thus, p16^{INK4a} loss should induce cell proliferation. This suggests that despite LANA expression, Rb function is not completely inactivated in PEL. Consistent with this hypothesis, when p16^{INK4a} expression is restored, PEL cells are rendered sensitive to growth inhibition. These observations suggest that additional mechanisms may be necessary to completely eradicate the function of Rb in the infected cell.

LANA can also interact with GSK-3 β , a kinase that phosphorylates and inactivates β -catenin by targeting it for ubiquitin-mediated degradation.²¹⁷ LANA binding to GSK-3 β induces the kinase to move from the cytosol to the nucleus, allowing for cytoplasmic accumulation of β -catenin. Cytosolic β -catenin can then interact with the transcription factor LEF, which relocates it to the nucleus, where this complex up-regulates proliferative genes (e.g., cyclin D and c-Myc). The correlation between LANA expression and β -catenin up-regulation in PEL is inhibited by RNA interference (RNAi)-mediated knockdown of LANA expression.²¹⁷ Additionally, LANA expression in other cell types induces S-phase entry.²¹⁷ LANA has also been reported to enhance the stability of the c-Myc protein through its effects on GSK-3 β nuclear localization. In LANA-expressing cells, inactivation of nuclear GSK-3 β inhibited c-Myc phosphorylation at threonine 58 and contributed to c-Myc stabilization by decreasing c-Myc ubiquitination.^{80,407}

LANA also impacts host gene expression through binding of multiple components of the transcriptional machinery. Gene expression profiling of LANA-positive B cells identified many host genes whose expression is dysregulated by LANA.⁵⁶¹ LANA can transcriptionally modulate genes in the Rb/E2F pathway^{14,561,709} (Fig. 65.7). Although LANA can

activate transcription of some cellular genes,^{14,561,709} LANA primarily mediates repression of transcription. LANA inhibits expression of TR-linked reporter genes, and when fused to the DNA binding domain of GAL4, LANA does hamper transcription of GAL4-dependent reporters.^{229,348,594} This effect is partly owing to the recruitment of the mSin3 co-repressor complex through binding to its SAP30 subunit.³⁴⁸ LANA also binds the co-activator CBP to repress transcription by inhibiting its histone acetyl transferase (HAT) activity.³⁹⁵ LANA binds and inhibits the activation function of ATF4,³⁹⁸ a sequence-specific transcriptional activator. Finally, LANA interacts with RBP-J κ (also referred to as CSL) and is targeted to RBP-J κ sites in the ORF50 promoter,³⁶¹ where it again mediates repression. Further, LANA can inhibit the activated intracellular domain of notch (ICN)-mediated transactivation of ORF50, thereby preventing lytic reactivation.³⁶³

The physiologic role of LANA-mediated repression might affect cell survival and/or proliferation. It may function in the repression of viral lytic cycle genes, thereby allowing for establishment and maintenance of viral latency. This likely also applies to the many other nuclear proteins that can bind to LANA—for example, the methyl CpG binding protein (MeCP2), the bromodomain-containing RING3 protein 2 (Brd2), nuclear matrix proteins, and heterochromatin protein 1.^{347,395,396,451,539}

vCyclin

As described previously, the KSHV latency transcripts also encode two other proteins in addition to LANA. ORF72 encodes vCyclin, which shows homology to cellular cyclin D. The vCyclin transcript is made by splicing out the LANA gene, yielding a bicistronic ORF72 + 71 transcript whose 5' gene encodes vCyclin (see Fig. 65.5). Similar to its cellular homolog, vCyclin can bind and activate cdk6.¹²⁶ However, it differs from host cyclin D in that it is less active on cdk4, and although both can induce cdk6-mediated Rb phosphorylation, the viral cyclin can also activate phosphorylation of p27, histone H1, nucleophosmin (NPM), Id-2, and cdc25a.^{157,242,386} NPM is a nuclear phosphoprotein and a histone chaperone involved in transcription and chromatin organization. Phosphorylation of NPM by the vCyclin/cdk6 complex allows NPM to interact with LANA and regulate viral latency.⁵⁸⁵ Exogenous vCyclin expression can promote S-phase entry in 3T3 cells and also overcome Rb-mediated cell cycle arrest triggered by cdk inhibitors⁶⁴⁴ (Fig. 65.7). Overall, the vCyclin/cdk6 complex is less sensitive to inhibition by cdk inhibitory proteins such as p27, p21, and p16. Inactivation of p27 is mediated by phosphorylation.⁵⁸⁶ Moreover, p27 phosphorylation by vCyclin-cdk6 targets it for degradation, further impairing p27 control of cdk6.^{196,435} vCyclin can also interact with cdk9, leading to increased phosphorylation of p53 at serine 33, which results in cell cycle arrest.¹²³ Consistent with this report, overexpression of vCyclin in multiple cell types induces apoptosis.⁵⁰⁸

However there are some discrepancies. For example, although vCyclin overexpression destabilizes p27, PEL routinely display high levels of p27 expression.¹⁰⁰ Establishing stable cell lines expressing vCyclin has been difficult because such cells often undergo apoptosis, especially if they display high levels of cdk6.⁵⁰⁸

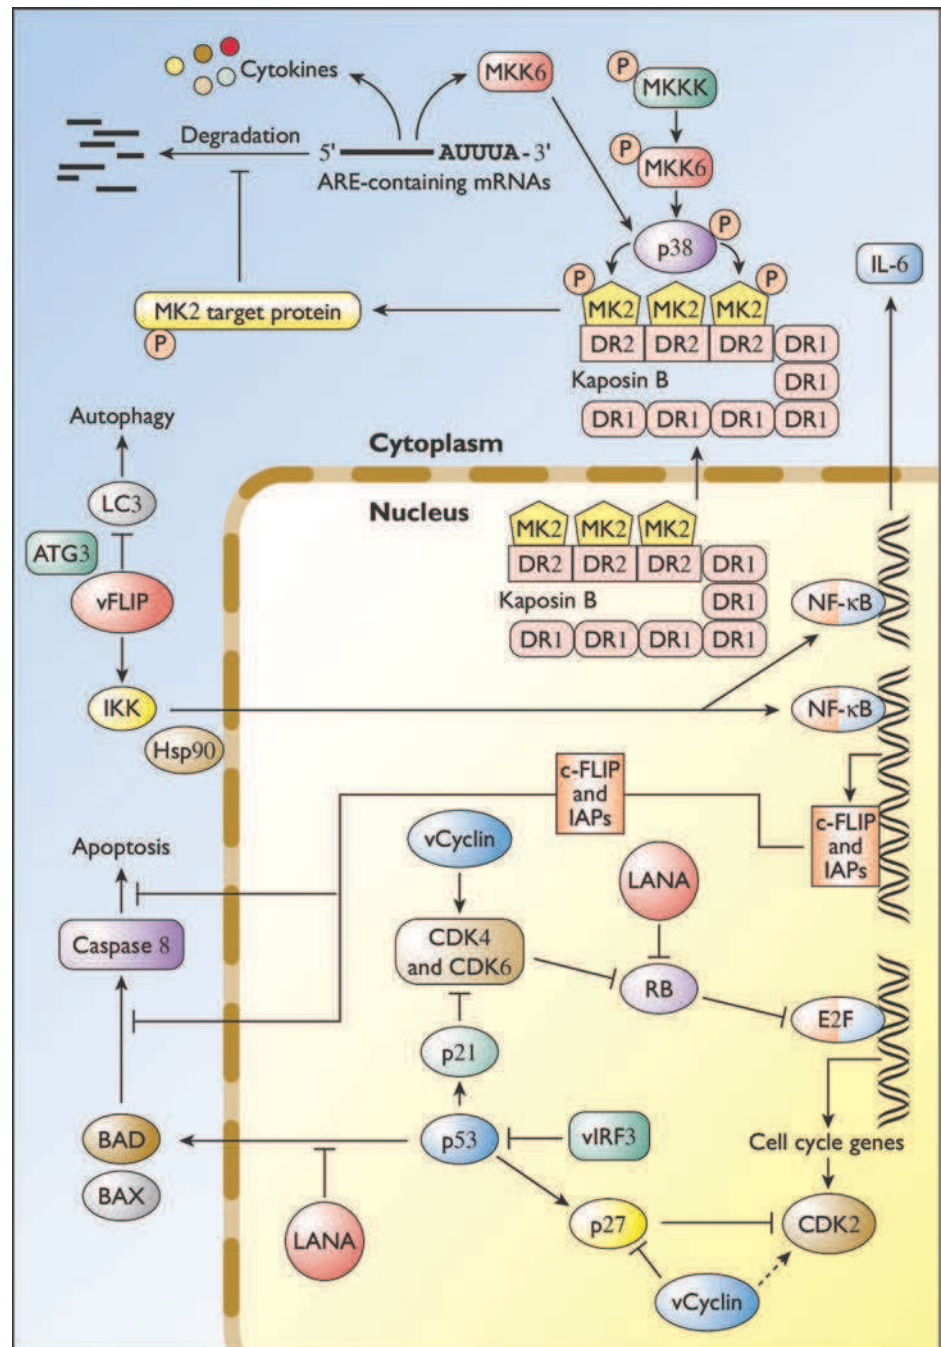

FIGURE 65.7. Functions and interactions of latent viral proteins. Latency-associated nuclear antigen (LANA), vCyclin, vFLIP, kaposin, and vIRF-3/LANA-2 act in concert to inhibit apoptosis and enhance cell survival and proliferative loops.

vCyclin-induced apoptosis is linked to the inactivation of the antiapoptotic factor bcl2⁵⁰⁹ owing to its phosphorylation by vCyclin/cdk6. Thus, the low levels of vCyclin protein expression during latency likely represent one way the virus avoids triggering cellular apoptosis. Alternatively, another viral protein might ablate this apoptotic effect. Along this vein, it is of interest that Verschuren et al^{667,668} demonstrated that loss of p53 allows for cell survival in the presence of increased levels of vCyclin. Moreover, when vCyclin was expressed in B cells in transgenic mice, lymphomas developed only in animals deleted for p53.^{667,668} This suggests that the functional inactivation of p53 by LANA during latency (or by vIRF3; see later discus-

sion) might unmask the oncogenic potential of vCyclin. The antiapoptotic effects of vFLIP may also alleviate vCyclin-induced toxicity.

A different line of transgenic mice was made in which vCyclin was expressed in only the lymphatic endothelium through the use of the vascular endothelial growth factor (VEGF)-R3 promoter. These mice displayed severe lymphatic dysfunction and developed chylous ascites. The reason for this is unknown but might reflect the toxicity of vCyclin overexpression.⁶³⁸ Indeed, in human dermal microvascular endothelial cells, vCyclin induces replicative stress leading to the development of senescence and activation of the DNA damage response.³⁴²

vFLIP

KSHV vFLIP, the product of ORF71, also referred to as K13, is the viral homolog of cellular FLIP (FLICE [FADD-like interleukin-1 beta-converting enzyme, now called caspase-8] inhibitory protein). KSHV vFLIP is composed of two death effector domains (DEDs) one right next to the other, which mediate homotypic protein–protein interactions with other DED-containing proteins. DEDs are present in the adaptor protein FADD, which binds the death receptor FasR. Initiator caspases, including caspase-8 and -10 in humans, also contain two tandem DEDs, and caspase-8 is a critical player in Fas-mediated death induction. Among the cellular FLIPs, the two predominant forms are the long form (FLIP_L) and the short form (FLIP_S). vFLIP is structurally more similar to FLIP_S, as they both lack a caspase-like domain present in FLIP_L. The long form includes a caspase-like domain, whereas the short form lacks this domain. After FasR is bound by Fas ligand present outside the cell, FasR binds FADD, which in turn recruits and activates procaspase-8, via interactions between the DED domains of FADD and the caspase, generating the death-inducing signaling complex (DISC). Caspase activation subsequently triggers the apoptotic cell death program. This process can be blocked by competitive binding by the cellular FLIP proteins.

Virally encoded FLIPs were first discovered in poxviruses and other herpesviruses, where they blunted Fas-mediated killing by preventing caspase-8 recruitment to the DISC.⁶⁵⁰ Procaspase-8 can also be bound and inhibited. Several early studies have supported this mechanism for KSHV vFLIP.^{30,43,183} However, the ability of vFLIP to block Fas-mediated killing has been questioned¹⁴¹; consistently observed in all studies is the observation that KSHV vFLIP up-regulates antiapoptotic transcription factor NF- κ B^{128,258,450,639,640} and that vFLIP can be found bound to NEMO (also referred to as IKK γ) in PEL cells.^{208,259,408} This complex activates IKK, leading to I κ B phosphorylation and the release of active p65-p50 NF- κ B heterodimers. In addition, vFLIP also increases accumulation of the p52 subunit of NF- κ B, indicating that vFLIP can activate the alternate pathway of NF- κ B, which involves the proteolysis of p100 to p52.⁴⁴⁸ These findings are concordant with the observations that (a) PEL exhibit high levels of NF- κ B activity, and inhibition of this pathway induces cell death,³³⁰ and (b) small interfering (siRNA)-mediated knockdown of vFLIP promotes apoptosis in PEL.^{243,258} It therefore appears that the key role of vFLIP during PEL latency is the activation of an antiapoptotic program through the up-regulation of NF- κ B activity. Notably, among the cellular genes that are clearly regulated by NF- κ B, and therefore by vFLIP, are the cellular inhibitor of apoptosis 1 and 2 proteins, as well as cellular FLIP,²⁵⁸ making studies to determine whether vFLIP can inhibit FAS-mediated apoptosis complicated, as the effect might be direct or indirect. Two different transgenic mouse models for vFLIP have been made. In one of these, where vFLIP was expressed in all B and T cells, mice showed enhanced responses to mitogenic stimuli and, not surprisingly, an increased incidence of lymphoma in a small proportion of mice, although in a much higher proportion when bred with c-Myc transgenic mice.^{7,141} In the second report, a conditional knock-in system was used to express vFLIP in all B cells, or specifically in GC B cells.³⁰ These mice developed lymphadenopathy with increased numbers of lambda light chain–expressing plasmablasts, reminiscent of

MCD, as well as tumors of B-cell origin with high frequency, albeit with an abnormal immunophenotype and histiocytic transdifferentiation. Consistent with these observations, treatment of PEL cell lines with Bay11-7082, an NF- κ B inhibitor, results in apoptosis *in vitro* and tumor responses in a mouse model of PEL.³²⁹ Furthermore, the proteasome inhibitor bortezomib blocks I κ B proteolysis, impairs NF- κ B activation, and triggers apoptosis of PEL cell lines^{4,16,449} and in a xenograft mouse model using freshly isolated human PEL cells into the peritoneal cavities of NOD/SCID mice without *in vitro* cell growth. These data suggest that this drug might have therapeutic efficacy in PEL.⁵⁸⁹ A single case report has documented a good response of a patient treated with bortezomib in combination with pegylated liposomal doxorubicin and rituximab.⁶⁰⁵

We have discussed the antiapoptotic effects of NF- κ B, which likely provides the selective force for maintaining KSHV vFLIP. However, NF- κ B is a key positive regulator of inflammatory responses.³⁸⁸ It seems paradoxical that a latency program in herpesviruses, designed for cryptic persistence, would call attention to itself by activating inflammation. However, vFLIP has additional effects, which may at least partially explain this paradox. In addition to the antiapoptotic function that is thought to be mediated mainly by NF- κ B–regulated genes, vFLIP has been shown to protect cells from autophagy by binding to Atg3.^{373,378a} In endothelial cells, it is required for the spindling seen after infection with KSHV.²⁵² It also contributes to prevention of detachment-induced apoptosis (anoikis) in endothelial cells.¹⁹⁵ Moreover, NF- κ B activation may not be the only function of KSHV vFLIP. The protein also binds to RIP and TRAF2 upstream of IKK, and TRAF binding results in JNK activation.^{17,259} Finally, NF- κ B activation by vFLIP may play other roles in KSHV biology.⁷⁷ It has also been shown that activation of NF- κ B hinders lytic gene expression and inhibition of NF- κ B activation induces lytic reactivation. Thus, vFLIP may play an important role in maintaining stable KSHV latency.

Kaposins

The locus for kaposin was initially identified by a screen for genes that were expressed during latency in PEL cell cultures.⁷³⁶ *In situ* hybridization using probes for kaposin mRNA revealed that kaposin is expressed at low levels in both uninduced body cavity–based lymphoma (BCBL)-1 cells and to some degree in latent KS spindle cells.^{629,636} Like several other latent loci, kaposin is also highly up-regulated during lytic replication.⁵⁷³

Kaposin mRNA encodes for three proteins owing to differential translation initiation⁵⁷³ (Fig. 65.8). At their 3' end, all kaposin messages contain a small ORF (ORF K12) encoding a highly hydrophobic 60 amino acid polypeptide called *kaposin A*. Kaposin A is found in intracellular membranes and the plasma membrane.⁶⁵² It is capable of transforming Rat-1 fibroblasts, and the resulting cell lines form tumors (fibrosarcomas) in nude mice.⁴⁸⁰ Kaposin A binds cytohesin-1, a guanine nucleotide exchange factor (GEF) for ARF GTPases, and a regulator of cell adhesion mediated by integrins. This interaction allows for GTP binding to ARF1. Because expression of a cytohesin-1 mutant deficient in guanine nucleotide exchange reverses transformation,³³⁶ this activity is likely to be important for transformation. Immediately upstream of the K12 ORF is a series of tandemly repeated 23-nucleotide, GC-rich elements known as DR1 and DR2. This region lacks AUG codons;

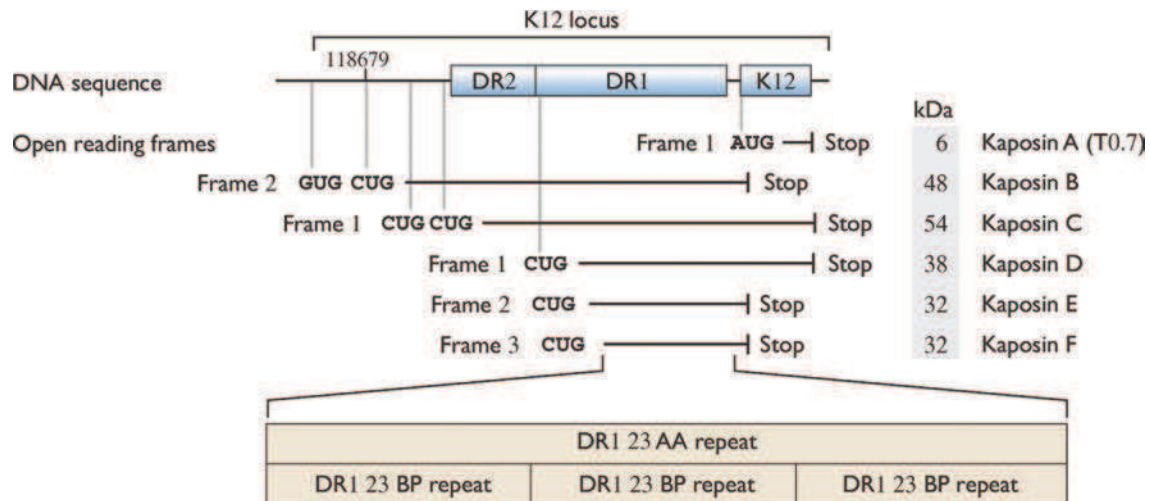

FIGURE 65.8. The coding capacity of the kaposin locus. **Top line:** Coding organization of kaposin messenger RNA. **Middle panel:** Protein products predicted from translation of each of the several CUG codons of kaposin. Kaposins A, B, and C are products of this locus. It is unclear as to whether the lower molecular weight species listed here as kaposins D, E, and F, which are regularly observed in infected cells, are in fact translated from the indicated CUG (as shown) or represent proteolytic end products of the larger kaposins.

however, multiple proteins are generated from this region by initiation at variant CUG codons. One of these initiates upstream of the DR2 repeat cluster and terminates after the DR1 repeats and encodes kaposin B, a nuclear protein that lacks the ORF K12 polypeptide region because of a stop codon in the reading frame. Another protein, kaposin C, similarly begins 5' to DR2 but in an alternative reading frame compared to kaposin B. Translation proceeds through the DR regions and ORF K12. This generates a transmembrane protein that contains the amino acid repeats (encoded by the DRs) fused to K12. Although the kaposins B and C DR sequences are in different frames, they share a common segment of repetitive sequence. Translation of an individual repeat induces the ribosome to enter the next repeat one nucleotide out of frame; after traversing three such repetitive sequences, the ribosome reverts back to the initial frame (see Fig. 65.8). Thus, the repeat regions of kaposin B and C share two sets of common 23 amino acid repeats, flanked on both sides by sequences unique to each protein. Consequently, kaposin C is partly a membrane-bound kaposin B isoform.

Kaposin B can bind and activate MAP kinase-associated protein kinase 2 (MK2) as well as the upstream kinase, p38 MAP kinase.⁴⁵⁷ MK2 is the major target of p38, which is a stress-inducible kinase. MK2 regulates the stability of cytoplasmic mRNAs that contain AU-rich elements (AREs) in their 3' UTRs. AREs are found in many cytokine mRNA transcripts (e.g., interleukin [IL]-1, -3, -4, -6, tumor necrosis factor [TNF]- α , and GM-CSF), as well as other growth factors (e.g., VEGF) and oncogenes (e.g., c-Myc). ARE mRNAs are highly unstable; however, activation of the MK2/p38 kinases inhibits their turnover and thereby enhances the levels of these cytokine mRNAs.^{343,707} Thus, by up-regulating MK2, kaposin B prolongs the half-lives of ARE-bearing reporter transcripts and increases cytokine production⁴⁵⁷ (see Fig. 65.7). Both the DR1 and DR2 repeat regions are essential for kaposin B's func-

tion.⁴⁵⁶ It was recently shown that kaposin B also enhanced stability of PROX1, a regulator of lymphatic endothelial differentiation that is up-regulated upon KSHV infection of endothelial cells. The PROX1 mRNA transcript also contains an ARE, and kaposin B enhances its stability.⁷²⁷

K10.5/vIRF3/LANA2

The KSHV genome has four genes that encode proteins of the IRF family. The family of IRFs are cellular transcription factors, several members of which (e.g., IRF3 and IRF7) transcriptionally activate type I IFNs and IFN-stimulated genes. The viral IRF homologs (vIRFs) are encoded by ORFs K9 through K11 (see Fig. 65.3), suggestive of the fact that they arose by duplication of one or more ancestral genes, plausibly obtained from the cellular genome. All vIRFs are lytic proteins, except for vIRF-3 (ORF K10.5), which encodes a nuclear protein that is expressed in latent PEL but not in KS spindle cells.^{181,419,567} For this reason, vIRF3 is also called *latency-associated nuclear antigen 2* or LANA-2.

vIRF3 expression inhibits the IRF3/7-mediated induction of the IFN- α 4 promoter in murine cells and hinders the ability of these cells to mount an IFN response to RNA virus infection.⁴¹⁹ vIRF3-expressing cells have decreased activation of protein kinase R (PKR), another activator of the IFN response.²⁰⁵ KSHV vIRF3 can also bind and inactivate the function of cellular IRF7.³¹³ This leads to the suppression of IFN- α -related activities.³¹³

vIRF3 can interact with a suppressor of c-Myc activity, MM-1 α , thereby sequestering it from interacting with and inhibiting the function of c-Myc.⁴¹⁸ Furthermore, vIRF3 also inhibits cellular IRF5 function,⁷⁰³ preventing its ability to induce p53-independent apoptosis and p21-mediated cell cycle arrest.⁷⁰³ In concordance, vIRF3 has also been shown to bind and inactivate p53.⁵⁶⁷ This vIRF3 function may function in prolonging the life span of KSHV-infected B cells, particularly

in the context of vCyclin expression.⁶⁶⁸ Indeed, central to its expression in PEL, a critical finding was that vIRF3 expression was required for PEL survival.⁷⁰⁴ Knockdown of vIRF3 expression in PEL hampered cell proliferation and increased activity of caspase-3 and -7.⁷⁰⁴ Additionally, these effects were seen even in the context of dually infected EBV- and KSHV-positive PEL lines.⁷⁰⁴ In endothelial cells, vIRF3 appears to play a role in angiogenesis. Hypoxia-inducible factor-1 (HIF-1), a regulator of angiogenesis, is composed of an oxygen-sensitive α subunit and a constitutively expressed β subunit. vIRF3 can bind the HIF-1 α subunit to stabilize it under normoxic conditions and increase the expression of VEGF and angiogenesis in endothelial cells.⁶⁰³ Thus, vIRF3 appears to play a key role in cell survival and angiogenesis in the context of viral latency, and perhaps angiogenesis in KS lesions (see Fig. 65.7).

Viral microRNAs

miRNAs are 21 to 23 nucleotide long RNAs that regulate gene expression via base pairing to their mRNA targets. miRNAs are generated from the cleavage of larger transcripts named *pri-miRNAs* via a processing pathway involving a ribonuclease (RNase) III-like endonuclease named *Drosha* located in the nucleus. These *pri-miRNAs* contain an imperfect inverted repeat that is cleaved by *Drosha* into a 65-nucleotide hairpin called a *pre-miRNA*, which is then transported to the cytoplasm where it is recognized by another RNase III-like endonuclease named *Dicer*. *Dicer* cleaves off the loop of the hairpin, thereby generating a partial duplex RNA molecule, which can bind to its target mRNAs. One strand of the RNA duplex is transferred to a cytoplasmic complex named *RNA-induced silencing complex* (RISC). In general, if base pairing of the miRNA to the target is perfect, then RISC cleaves the target mRNA. However, if base pairing of the miRNA to the target is imperfect, then RISC modulates translational repression of the target mRNA either through inhibiting translational initiation or elongation, or deadenylation (reviewed in 613).

Following the seminal discovery of viral miRNAs,⁵³¹ KSHV was found to encode 12 *pre-miRNAs* that arose from transcripts in the latency region^{87,257,531,579} (see Fig. 65.5). The miRNAs derived from these hairpins are designated as miR-K1 through miR-K12. Some of these *pre-miRNAs* (e.g. miR-K3, 4, 6, 9) donate each of the two arms of the hairpin to RISC, thereby giving rise to two mature miRNAs from each *pre-miRNA*. Each member of the pair is referred to as “5p” or “3p” to indicate its origin from the 5′ or 3′ segment of the hairpin. Additionally, the miR-K10 miRNA undergoes RNA editing at a single site in the seed sequence generating two different miRNAs (miR-K10a and miR-K10b). Thus, although there are 12 *pre-miRNA* transcripts arising from the KSHV genome, these lead to the generation of 17 mature miRNAs. These miRNAs are present in KS and PEL.^{504,506} There is strong sequence conservation in the genomic sequences that encode for these miRNAs, and only a subset of *pre-miRNAs* displayed single nucleotide polymorphisms (SNPs) that could affect their biogenesis.⁴³⁸

There has been a flurry of papers identifying putative functions for the KSHV miRNAs since their discovery. miR-K11 was found to contain an identical seed sequence to that of cellular miRNA miR-155.^{245,614} Viral miR-K11 was found to suppress known targets of cellular miR-155, including the transcriptional repressor BACH1, the proapoptotic protein

BIRC4BP/XAF1, and the cell cycle regulator FOS.^{245,614} Using a transcriptional profiling approach, another group identified that the target for miR-K5 was a proapoptotic Bcl2-associated factor named *BCLAF1*. Moreover, additional KSHV miRNAs including miRs K9, K10a, and K10b were also found to target BCLAF1. Repression of BCLAF1 expression by the KSHV miRNAs was found to be important for cell survival to apoptotic stimuli,⁷⁴⁴ as was the down-regulation of tumor necrosis factor–like weak inducer of apoptosis (TWEAK) receptor, a proapoptotic protein that is targeted by miR-K12-10a (also known as miR-K10a).² miR-K1 has been shown to down-regulate p21, a protein that induces cell cycle arrest,²⁴⁴ and also to target I κ B α .³⁷⁸ Moreover, miR-K12-3 and miR-K12-7 (also referred to as miR-K3 and miR-K7, respectively) down-modulate C/EBP β p20 (LIP), an isoform of C/EBP that represses IL-6 and IL-10 expression. This results in up-regulation of these cytokines in cells from the myeloid lineage.⁵⁴⁷ Curiously, miR-K12-7 (also referred to as miR-K7) has also been shown to down-regulate the stress-induced natural killer (NK) cell ligand MICB⁴⁸⁶ as a mode of immune evasion from the innate immune system. Thus, a single viral miRNA (i.e., miR-K12-7) appears to target different mRNA transcripts to ensure virus survival within the infected cell. One study also looked at gene expression profiling in cells stably expressing all KSHV-encoded miRNAs.⁵⁸⁰ They found that 81 genes were changed in the presence of the viral miRNAs. One of these proteins is the tumor suppressor protein, thrombospondin 1 (THBS1), whose protein levels were decreased over 10-fold.⁵⁸⁰ Reduced THBS1 expression in the presence of viral miRNAs led to decreased transforming growth factor (TGF)- β activity, suggesting that the viral miRNAs contribute to tumorigenesis and angiogenesis.⁵⁸⁰

It is known that KS is comprised of poorly differentiated endothelial cells, expressing markers of both lymphatic endothelial cells (LECs) and blood vessel endothelial cells (BECs). KSHV-encoded miRNAs appear to contribute to transcriptional reprogramming by silencing the cellular transcription factor musculoaponeurotic fibrosarcoma oncogene homolog (MAF).²⁷³ MAF is expressed in LECs but not in BECs, where it functions as a transcriptional repressor of BEC-specific genes to maintain the differentiation status of LECs. KSHV-infected LECs show an up-regulation of BEC-specific genes through miRNA-dependent down-regulation of MAF.²⁷³ Additional approaches have used more sophisticated techniques to identify miRNA targets on a global scale—for example, immunoprecipitation of Argonaute (Ago) protein-containing RISC followed by microarray analysis (RIP-Chip).^{184,244a,292a} In summary, KSHV-encoded miRNAs can influence the differentiation status of a cell in a manner similar to certain cellular miRNAs, and this suggests that the viral miRNAs may contribute to the development of viral malignancies via reprogramming the differentiation pathway of the infected cell.

In addition to their roles in cell survival and oncogenesis, the KSHV viral miRNAs also play a key role in regulating the lytic-latent switch. Several studies have examined the role of viral miRNAs in controlling this switch, and although all of these studies find that the miRNAs enhance latency and suppress lytic replication, the mechanism by which this occurs is different in each case. For example, miR-K9* has been reported to target the 3′ UTR of the ORF50 transcript, thereby enhancing latency and preventing viral reactivation.⁴⁴ Consistent with

this finding, a KSHV BAC with 10 of the 12 viral miRNAs deleted displayed elevated levels of viral lytic genes, including ORF50.⁴¹⁴ However, this group reported that another miRNA, miR-K12-5 (also referred to as miR-K5), could repress the ORF50 mRNA transcript.⁴¹⁴ Additionally, miR-K12-4-5p (also referred to as miR-K4-5p) was found to target Rbl-like protein 2 (Rbl2), a known repressor of DNA methyl transferase 3a and 3b (DNMT3a/b). miR-K12-4-5p reduced Rbl2 protein expression and increased DNMT1, -3a, and -3b mRNA levels to regulate genome-wide epigenetic reprogramming.⁴¹⁴ In further confirmation of the role of the viral miRNAs in suppressing lytic replication, deletion of 14 miRNAs from the KSHV genome also significantly enhanced viral lytic replication as a result of reduced NF- κ B activity.³⁷⁸ Finally, yet another group found that miR-K3 can enhance viral latency by inhibiting expression of nuclear factor I/B, a transcription factor that can activate the ORF50 promoter.⁴¹²

Genes Expressed at Low Levels During Latency but Highly Up-regulated During Lytic Replication

As mentioned earlier, K1 and vIL-6 were initially considered to be lytic proteins; however, several publications now demonstrate that their transcripts are expressed at low levels during latency and are highly up-regulated during lytic replication.^{67,93,118,521,628,679}

A recent publication used tightly latent cell lines that displayed very low levels of spontaneous lytic reactivation to perform array-based transcript profiling and limiting dilution RT-PCR in these cells. They found that both K1 and K2/vIL-6 genes were expressed under latent conditions.¹¹⁸ Additionally, the K1 promoter is active in multiple cell types in the absence of ORF50/RTA protein.^{67,68,118,679} It is likely that owing to their potent signaling properties, both K1 and vIL-6 need to be expressed at low levels in infected cells.

K1

ORF K1 is situated at the left-hand end of the genome and encodes for a type I transmembrane protein, whose signaling function is analogous to the B-cell antigen receptor complex. K1 is found in the endoplasmic reticulum and also on the plasma membrane. It contains a highly variable, glycosylated,^{502,751} N-terminal ectodomain, a transmembrane region, and a cytoplasmic tail that sports an immunoreceptor tyrosine-based activation motif (ITAM).³⁷⁰ This structure, also found in B-cell receptor (BCR) and T-cell receptor (TCR) signaling complexes, contains two tyrosine residues separated by characteristic spacing. Activation of the BCR by antibody binding results in phosphorylation of tyrosines by Src kinases. Phosphorylation creates binding sites for Syk kinase, which upon activation mediates downstream signaling, including PLC γ activation, calcium release and NFATc activation, among other events. The K1 protein signals in a similar fashion; however, its activity appears to be constitutive because it signals in the absence of a ligand.^{360,370} Although it is possible that the K1 ectodomain binds to a ubiquitously expressed cell surface protein, constitutive activation is more likely due to self-oligomerization mediated by cysteine residues in the K1 ectodomain. K1 aggregation leads to ITAM phosphorylation, Syk kinase recruitment, and increased NFATc and AP-1 activity similar to what occurs upon BCR activation. Moreover, the activated K1 tail can interact with other signaling proteins besides Syk, including PI3-kinase (via its p85 regu-

latory subunit), Lyn, RAS-GAP, PLC- γ 2, vav, and c-Cbl.^{360,368,654} PI3K activation results in phosphorylation and activation of Akt kinase.⁶⁵⁴ Activated Akt phosphorylates the forkhead (now known as FOXO) transcription factors, sequestering them in the cytoplasm (Fig. 65.9). Because FOXOs induce apoptosis, this phosphorylation is an antiapoptotic event, and K1 expressing cells exhibit greater resistance to apoptosis induced by both Fas ligand and the expression of FOXO proteins.⁶⁵⁴ K1's effect on apoptosis may also be linked to its ability to bind to chaperones. K1 was shown to interact with heat shock protein 90-beta (Hsp-90beta) and endoplasmic reticulum-associated Hsp40 (Erdj3/DnaJB11) by tandem affinity purification.⁶⁹⁵ K1 expression and antiapoptotic function highly depends on Hsp90 and Hsp40/Erdj3, because knockdown of these proteins, as well as pharmacologic inhibitors of Hsp90, dramatically reduces K1 expression.⁶⁹⁵ Furthermore, in B cells, K1 expression hinders the surface transport of the BCR,³⁶⁷ and this may be a means by which KSHV puts the infected B cell under the control of the virus rather than the control of the BCR. In this manner, stimulation of BCR signaling does not jeopardize the viral life cycle. K1 signaling function in B cells has been shown to be regulated by its endocytosis, and these two events are intertwined.⁶⁵³

K1 is capable of transforming rodent fibroblasts and substituting for the STP oncogene in the context of HVS-mediated transformation of T cells.³⁷¹ Lymphomas and sarcomas are known to develop in K1 transgenic mice,⁵⁴⁴ and the lymphomas show activated Lyn kinase⁵⁴³ and are refractory to Fas-mediated apoptosis.⁶⁸² In epithelial and endothelial cells, K1 expression has been reported to induce the secretion of angiogenic factors, including VEGF and matrix metalloproteinase-9.⁶⁸⁰ K1 can activate the PI3K/Akt/mTOR pathway in endothelial cells and can immortalize and extend the life span of primary HUVEC in culture⁶⁷⁹ (see Fig. 65.9). K1 ITAM expression was needed to activate both the VEGF/VEGFR-2 and the PI3K/Akt signaling pathways in these cells. Thus, K1 appears to be important in KSHV-associated tumorigenesis and angiogenesis.

In the context of lytic replication, the ITAM of K1 has been shown to augment lytic reactivation from latency.³⁵⁹ However, others have shown that the K1 ITAM is needed to suppress TPA-mediated viral reactivation in the context of PEL cells, and this suppression may contribute to the establishment and/or maintenance of KSHV latency *in vivo*.³⁶⁹ These differences may be explained by the experimental conditions used in each model system.

vIL-6

Cellular human IL-6 (hIL-6) signals through a heterodimeric receptor composed of a signaling subunit (gp130) and a high-affinity ligand-binding subunit (gp80/IL-6R α). Following hIL-6 binding to this receptor complex, STATs 1 and 3 are activated. The signaling mechanism of the viral homolog vIL-6 differs from hIL-6 in that it does not need the gp80 subunit; rather, it binds directly to gp130 to trigger signal transduction (Fig. 65.10). This enables vIL-6 to act on a wider spectrum of cells than its human homolog.⁷² Although vIL-6 does not need gp80 to activate signaling, it can still interact with this subunit of the receptor complex, which appears to modulate vIL-6's activity.^{290,383,384}

FIGURE 65.9. Signal transduction pathways activated by Kaposi's sarcoma-associated herpesvirus encoded transmembrane proteins K1, K15, and viral G protein-coupled receptor (vGPCR). Activation of the PI3K and mitogen-activated protein (MAP) kinase pathways by viral signaling proteins leads to enhanced production of cytokines and growth factors, cell proliferation, and inhibition of cell death.

IL-6 promotes B cell differentiation to plasma cells and also impairs B-cell apoptosis in response to apoptotic-inducing signals. vIL-6 shares the antiapoptotic activities of cellular IL-6 on B cells (including PEL cells),³¹² thus implicating vIL-6 in PEL and MCD pathogenesis.^{510,522}

Ectopic expression of vIL-6 in immortalized mouse fibroblast lines is linked to increased angiogenesis in the fibrosarcomas when these lines are transplanted into nude mice.¹⁹ Increased angiogenesis owing to VEGF induction by vIL-6 is an activity shared with cellular IL-6.^{19,146,406} In PEL, vIL-6 expression was shown to be selectively activated by IFN- α in the absence of full lytic replication. vIL-6 was also shown to blunt IFN signaling in these cells. In endothelial cells, vIL-6 expression caused an induction

of angiopoietin 2, a proangiogenic and lymphangiogenic factor.⁶⁶¹

Several groups have shown that vIL-6 can be localized to the endoplasmic reticulum,^{129,130,460} where it still retains "intracrine" signaling activity by interacting with gp130 intracellularly. The endoplasmic reticulum-resident chaperone protein calnexin plays a role in endoplasmic reticulum localization of vIL-6.¹²⁹ Intracellular vIL-6 appears to be functional in the autocrine promotion of proliferation and survival of PEL. Additionally, secreted vIL-6 is completely N-glycosylated, and this glycosylation is required for optimal conformation of the protein and optimal signaling.^{167,168,460}

Although a vIL-6 deletion mutant of KSHV did not affect viral latency or reactivation,¹³⁵ knockdown of vIL-6 expression

FIGURE 65.10. Kaposi's sarcoma-associated herpesvirus viral interleukin 6 (vIL-6) activates interleukin 6 receptor signaling by directly binding and activating the gp130 subunits of the IL-6 receptor complex. This leads to increased cell survival, proliferation, and induction of proangiogenic factors.

in PEL cells led to markedly reduced cell growth,¹³⁰ suggesting that vIL-6 likely plays an important role in PEL proliferation. Taken altogether, vIL-6 can contribute to KSHV pathogenesis through an autocrine manner during latency by augmenting survival and proliferation (see Fig. 65.10). During lytic replication, vIL-6 may function in a paracrine manner to promote survival of uninfected cells.

Lytic Phase

The default pathway for KSHV is latency. Hence, lytic infection, in cell culture, is most often studied by using compounds to induce reactivation from latency. In PEL cell lines, this is achieved by treatment with phorbol esters (TPA) or HDAC inhibitors (sodium butyrate, valproic acid), which will induce lytic reactivation in approximately 30% of PEL as judged by lytic protein expression. Transfected RTA expression plasmids or chemically induced RTA can also be used to induce more uniform reactivation.⁴⁸⁹ When immunofluorescence assays (IFAs) for late lytic proteins (e.g., ORF K8.1) are utilized, only half of the cells are positive, even at very late times. Thus, not every entry into lytic infection is completed successfully, and abortive lytic infection occurs some or most of the time. We

currently do not comprehend why many of these reactivated PEL cells fail to enter the lytic cycle when treated with HDAC inhibitors or TPA, and why only a fraction of cells in culture undergo lytic replication. One possibility is that many cells do not support the transmission of the inducing signal, or that the signal itself is ineffective or inhibitory in cells that do not support replication. Additionally, when PEL cell lines are cultured for many weeks in tissue culture, they lose efficient inducibility by TPA and HDAC inhibitors. Similarly, passage of stable PEL cell lines with drugs such as hygromycin and neomycin also hinders induction by TPA and HDAC inhibitors. Again, although we are not clear on why this happens, it is important to work with cells at low passage.

In addition to PEL, other latently infected cell lines, including 293, Vero, HFFs, and TIME cells,³⁵⁷ can be induced, whereas other lines (e.g., HeLa, SLK) into which a KSHV genome has been transfected are only transiently inducible by chemical means.^{15,39} However, inducible or forced expression of the lytic switch protein, RTA, can induce reactivation in a much wider array of lines than chemical activation.^{39,483,489} Finally, it was recently shown that the touselike kinases (TLK) suppress KSHV reactivation in B cells.^{178a}

Epigenetic Regulation of the Latent-Lytic Switch

Recently, several groups reported the presence of genome-wide epigenetic marks on the viral episome and their involvement in the regulation of the switch between latency and lytic replication.^{262,414,655} Histone modifications associated with the KSHV latent genome are involved in the regulation of latency, and also control the temporal and sequential expression of genes during the viral lytic life cycle. Activating histone modifications include acetylated H3 (AcH3) and H3K4me3, whereas repressive histone modifications include H3K9me3 and H3K27me3. The latent viral genome contains both activating and repressive histone modifications. These marks are mutually exclusive across the latent genome.^{262,655} For example, under latent conditions, the genomic region encoding the lytic gene ORF50/RTA contained activating H3K4me3 and repressive H3K27me3 marks that rapidly changed to increasing AcH3 and H3K4me3 activating modifications and decreasing H3K27me3 modifications upon viral reactivation.^{262,655} Additionally, latency-specific histone modification patterns were established following *de novo* infection, and there was rapid and widespread deposition of H3K27me3 marks across latent genomes.²⁶² H3K27me3 is a bivalent modification that can repress transcription despite the simultaneous presence of activating marks on the genome.²⁶² It was also observed that EZH2 (the H3K27me3 histone methyltransferase) was present on the entire KSHV genome during latency but was dissociated from the genome during ORF50-mediated reactivation. EZH2 inhibition or knockdown and expression of H3K27me3-specific histone demethylases all induced the lytic life cycle in PEL.⁶⁵⁵ Chromatin immunoprecipitation (ChIP) assays revealed that KSHV genomes are highly methylated at CpG residues (except for the LANA promoter [131]), leading to the establishment of characteristic global DNA methylation patterns. These types of studies are still in their infancy; however, thus far they have revealed that the viral genome is epigenetically modified in the latent state so that transcription is generally repressed. At the same time, parts of the genome also contain activating histone modification, and the virus may

FIGURE 65.11. Map of known transcripts emanating from the main lytic region of Kaposi's sarcoma-associated herpesvirus. Top line shows a map of the major genomic open reading frames (ORFs) (arrows). ORF50, K8, and K8.1 are encoded on a polycistronic transcript. All messenger RNAs are polyadenylated at the indicated positions. (Modified from Yuan Y, Renne R. DNA tumor viruses. In: Damania B, Pipas J, eds. *Organization and Expression of the Kaposi's Sarcoma-associated Herpesvirus Genome*. New York: Springer Press; 2009:469–493.)

therefore be poised to enter the lytic cycle once reactivation is triggered. Additionally, ORF50/RTA lytic transcription is actively repressed by LANA during latency, which is relieved upon lysine acetylation of the LANA protein.⁴¹³

Immediate-Early Gene Expression

A single viral protein named RTA, encoded by ORF50, controls reactivation from latency and the induction of lytic replication. RTA is the key lytic switch protein as deduced from two types of experiments: (a) expression of ectopic RTA by itself is sufficient to induce reactivation from latency^{246,423,641}; and (b) knocking out ORF50 function, either by dominant-negative ORF50 mutants⁴²² or by removal of ORF50 from the viral genome,⁷²¹ prevents reactivation from latency. Thus, ORF50/RTA is the critical protein required for the induction of lytic replication. Several experiments show that (a) ORF50 is the first transcript to appear following chemical induction with TPA or PEL,^{423,643} (b) the RTA/ORF50 promoter is inducible by TPA, and (c) lytic induction is linked to demethylation of the ORF50 promoter.^{131,415} ORF50 is a canonical IE protein, as it is transcribed in the presence of cycloheximide.^{596,641,739} ORF50 is part of a polycistronic transcript encoding for both K8 and K8.1 genes (Fig. 65.11).

ORF50/RTA

ORF50/RTA is a viral transcription factor. Its sequence and function is highly conserved among the rhadinoviruses.¹⁶¹ KSHV RTA has an amino-terminal DNA binding domain and a carboxy-terminal activation domain. A fusion of the ORF50 activation domain with a GAL4 DNA binding domain results in robust activation of GAL4 responsive promoter elements. ORF50 is phosphorylated on its C-terminal activation domain during viral replication. Moreover, phosphatase-treated ORF50 runs at a higher mobility than its predicted molecular weight, suggesting that additional posttranslational modifications must exist.⁴²² ORF50 forms tetramers and higher-order multimers in solution and the amino-terminal proline-rich, leucine heptapeptide repeat (LR) of ORF50 is necessary, but not sufficient, for oligomerization. Mutagenesis of this LR region revealed that ORF50 tetramers are sufficient for transactivation and viral reactivation and that ORF50 mutants are unable to form tetramers

but can still form higher-order multimers and are either non-functional or reduced in function.⁷⁸

ORF50 has been shown to bind to at least 19 sites in the KSHV viral genome.¹³³ These include regions of promoters, introns, and exons of KSHV genes, including ORF8, K4.1, K5, PAN, ORF16, ORF29, ORF45, ORF50, K8, K10.1, ORF59, K12, LANA, K14/vGPCR, and K15, the two origins of lytic replication OriLyt-L and OriLyt-R, and the miRNA cluster.¹³³ ORF50 expression leads to a strong activation of DE promoters (8- to 300-fold depending on the DE promoter). The highest activation by ORF50 is of the PAN (nut-1) promoter, which drives the transcription of a very abundant non-coding PAN RNA. Several mutagenesis experiments demonstrated that the ORF50-responsive site in the PAN promoter is the sequence AAATGGGTGGCTAACCTGTC-CAAAA upstream of the PAN RNA cap site. ORF50 has been shown to bind to this site *in vitro*.^{124,622} A similar sequence is located just upstream of the lytic kaposin transcript.^{573,623} Many other replication and transcription activator response elements (RREs) were identified using promoter-reporter co-transfection assays in the promoters of DE viral genes (e.g., tk, ORF57/MTA (mRNA transcript accumulation), K8/RAP, K2, K9, K14, DBP)^{132,175,176,308,389,391,421,683,690,694} and in one late promoter (gB).⁷⁴³ ORF50 can also up-regulate its own promoter.⁵⁷⁶ Many of the RREs share little sequence homology to the PAN/kaposin site or to each other. The RREs display low-affinity interactions with purified ORF50 protein in *in vitro* ORF50 binding assays.^{392,623,743} Although ORF50 binds to these sites with low affinity, many of these sites are very strongly induced by ORF50 in transient transfection cell-based assays (e.g., the ORF57/MTA and K14 promoters).⁶³⁰

Direct DNA binding by ORF50 is not the sole mechanism by which this protein can transcriptionally activate promoters. Two-hybrid screens of ORF50 binding cellular partners revealed that ORF50 can efficiently bind to the transcription factor, RBP-Jκ³⁸⁹ (also called CBF-1 or CSL). Indeed, RBP-Jκ recognition sites are found in many promoters of ORF50-responsive genes (e.g., K8/RAP, tk, PAN, ORF57/MTA, K14, LANA, and gB).^{389,391,447,686,690,743} In many of these promoters, RBP-Jκ sites lie adjacent to low-affinity ORF50 binding sites, suggesting that cooperative interactions may exist to enhance or stabilize the binding of ORF50 at these sites. Even reporter

genes that harbor synthetic RBP-J κ elements can be strongly activated by ORF50. This suggests that in addition to binding promoters through its sequence-specific DNA binding activity, ORF50 is also targeted to promoters through protein–protein interactions with RBP-J κ (as well as other transcription factors) bound at the promoter. RBP-J κ deleted fibroblasts are not supportive of ORF50-transactivation of many reporter genes, and KSHV-infected fibroblasts show reduced reactivation when ORF50 plasmid is transfected into these cells.³⁹⁰

RBP-J κ protein normally functions as a transcriptional repressor. ORF50 binding to RBP-J κ converts it from a repressor to an activator via ORF50's activation domain. In uninfected cells, RBP-J κ -directed repression is controlled by the Notch pathway through extracellular ligands that activate the transmembrane receptor protein Notch. Activation of Notch leads to the cleavage of its juxtamembrane domain, liberating its intracellular domain. The Notch intracellular domain moves to the nucleus, where it can bind RBP-J κ , converting it from a repressor of transcription to an activator of transcription. This phenomenon is similar to what happens with RBP-J κ and ORF50. Thus, KSHV has co-opted the Notch-RBP-J κ pathway to transactivate ORF50-responsive, RBP-J κ binding site containing promoters.

In EBV latency, two viral proteins—EBNA2 and EBNA 3C—also target RBP-J κ .^{251,568,675} Interestingly, ORF50 binds to RBP-J κ at two sites, and one of these is identical to the site bound by the Notch intracellular domain and EBNA2. The human Notch intracellular domain that constitutively activates RBP-J κ was expressed in PEL, and gene expression profiling showed that this domain robustly induced expression of several lytic viral genes but could not evoke the full repertoire of lytic viral gene expression normally induced by ORF50 expression.¹¹⁹ These results indicate that the control of viral gene expression by cellular Notch signal transduction only partially overlaps with ORF50,¹¹⁹ suggesting that RTA does more than merely mimic Notch and that some RBP-J κ elements in the viral genome have completely diverged from Notch signaling and now only respond to the viral transactivator (D. Dittmer, personal communication). This result is not surprising given that ORF50 has additional mechanisms of promoter targeting besides RBP-J κ sites (see later discussion). However, these results suggest that certain lytic genes can be activated in an ORF50-independent manner and under conditions when ORF50 is not expressed.

ORF50 can also interact with the transcription factor C/EBP α in the K8/RAP, ORF57/MTA and PAN promoters,^{683,684} and with Oct-1 in the ORF50 promoter.⁵⁷⁶ These interactions are important for ORF50 recruitment to these sites. Additionally, the binding of ORF50 to both Oct-1 and the K8 promoter leads to transactivation and viral reactivation, and the ORF50/Oct-1 interaction is necessary for optimal KSHV reactivation.¹⁰² Oct-1 also appears to mediate ORF50's interaction with cellular HMGB1 protein to up-regulate its own promoter.²⁷⁷ ORF50 can interact with STAT-3, inducing it to move to the nucleus to activate STAT-responsive genes.²⁶⁸ ORF50 can also interact with the protein MGC2663.⁶⁸¹ ORF50 binds proteins involved in histone acetylation (CBP and HDAC 1),²⁶⁷ the chromatin remodeling complex, SWI/SNF and the TRAP/Mediator complex, which enables interaction of RNA pol II with many transcription factors.²⁶⁶ Interactions with histone modeling proteins occur via the C-terminal activation domain of ORF50. Mutational studies show that

blocking these interactions prevents both transcriptional activation and lytic induction, confirming their importance for ORF50 function.

The spliced isoform of plasma cell transcription factor X box binding protein 1 (XBP-1s) can regulate the latency to lytic switch for KSHV.^{706,730} XBP-1s is normally absent in PEL; however, the induction of endoplasmic reticulum stress or hypoxia leads to production of XBP-1s and induction of the lytic cycle.^{159,730} XBP-1s binds to ORF50 and activates the ORF50 promoter in a synergistic manner.⁷⁰⁶ This interaction links lytic reactivation to plasma cell differentiation, which may be a mechanism whereby virus is produced in sites where immunoglobulin production is occurring, which include lymphoid tissues in the oral mucosa allowing virus to be shed into saliva.⁷⁰⁶

Although most research has focused on ORF50 transactivation, several reports show that ORF50 can also bind transcriptional repressors. As mentioned earlier, ORF50 binds HDAC1, resulting in repression of ORF50-mediated transactivation.²⁶⁷ ORF50 also binds to and is inhibited by poly(ADP-ribose) polymerase 1 (PARP-1) and Ste20-like kinase hKFC.²⁶⁹ It has also been shown that ORF50 can bind a cellular zinc-finger protein named K-RBP (or KSHV RTA binding protein). K-RBP is a transcriptional repressor that was shown to repress ORF50-mediated transactivation in a HDAC-independent manner.⁷²³ K-RBP could also suppress ORF50-mediated lytic reactivation. In a subsequent study, it was found that ORF50 could induce ubiquitin-mediated degradation of K-RBP, and ORF50 mutants that were defective in mediating K-RBP degradation were not as transcriptionally active as wild-type ORF50.⁷²⁴ Interestingly, the HSV-1 ICP0 transactivator and the HCMV pp71 transactivator also induce degradation of transcriptional repressors, suggesting that this may be a common mechanism by which many herpesviral lytic transactivators function.⁷²⁴ Additionally, transducin-like enhancer of split 2 (TLE2) is another repressor that interacts with ORF50 and inhibits its transactivation activity and ability to induce the lytic life cycle.²⁸² TLE2 appears to interact with the Pro-rich domain of ORF50, which is the same site that interacts with RBP-J κ .²⁸²

Finally, ORF50 has been shown to target IRF7 through ubiquitin-mediated degradation. The degradation is mediated through ORF50's recruitment of E3 ubiquitin ligase RAUL, which normally imparts K48-linked ubiquitins on IRF3 and IRF7.^{732,733} A summary of ORF50's interactions and functions is shown in Figure 65.12.

Other Immediate-Early Genes

Detailing the kinetics of viral gene expression in the presence of cycloheximide led to the identification of several other IE genes.^{592,739} Additional IE mRNAs encode for the products of ORF45 and K4.2, as well as a 4.5-kb RNA with partial complementarity to ORF29. (Note: Some reports refer to ORF45 and K8 as DE genes). Moreover, several transcripts antisense to ORF50 have been identified; however, their biological function is not known.^{423,739} The K8 gene has two promoters, one of which is activated in the IE phase and a second that is activated as a DE promoter through a ORF50-responsive RBP-J κ site in the promoter.⁶⁸⁶ Interestingly, the gene for KSHV ORF57/MTA, the homolog of HSV ICP27, is transcribed in the DE phase. The IE ORF45 protein functions to evade host innate immunity (discussed later).

K8/RAP

ORF K8 is a DE protein that is a member of the bZIP family of proteins, including EBV Zta and cellular transcription factors c-jun and c-fos. K8 is also referred to as replication-associated protein (RAP) or K-bZIP. ORF K8 and EBV Zta share some sequence similarity,^{253,403} although unlike EBV Zta, K8 does not induce viral reactivation of KSHV or enhance ORF50-mediated reactivation from latency.⁵⁴⁰ K8 has two promoters, one which is expressed during the IE phase and the other during the DE phase.⁶⁸⁶ Several spliced transcripts emanate from the DE promoter⁴⁰³; however, the major protein product, K8, is obtained from the fully spliced mRNA.⁵⁴⁰

Unlike ORF50, K8 does not appear to affect promoter activity to a great extent. Yet together with other proteins, K8 contributes to KSHV lytic replication and gene expression. For example, it binds to cellular bZIP proteins such as C/EBP-α, a

transactivator that is involved in the induction of differentiation and cell cycle arrest.^{712,713} K8 binding to C/EBP-α prolongs the half-life of C/EBP-α, thereby augmenting its function. The K8 promoter itself contains C/EBP-α binding sites, and there is a positive feedback loop for both K8 and C/EBP-α during viral replication.^{683,684} Further, because ORF50 also binds C/EBP-α, ORF50-driven transactivation of K8 is increased by K8. Stabilization of C/EBP-α also helps ORF50 activate other viral lytic promoters with C/EBP-α binding sites, such as the ORF50 and ORF57 promoters.^{683,684} Although K8 augments C/EBP-α function, K8's effect on most other transcription factors appears to be of a repressive nature. For example, K8 hinders CBP²⁹⁵ transactivation, and direct binding of K8 to ORF50 hinders its transactivation function on some promoters (e.g., ORF57 and ORF50 promoters), although PAN promoter activity is not affected.^{299,301,393} K8

can bind Ubc9, the SUMO conjugase protein leading to its own SUMOylation but perhaps also to SUMOylation of other transcription factors that interact with K8, although ORF50 is not SUMOylated in the presence of K8.²⁹⁹

K8 induces a prominent G1 arrest. Many herpesviruses exhibit cell cycle arrest during lytic replication, including KSHV.^{302,712} This is thought to occur in order to prevent cellular DNA synthesis from ensuing and thereby reduces the competition for energy and nucleotide pools. K8 induces cell cycle arrest by enhancing C/EBP- α accumulation through inhibition of E2F expression and increased expression of the cdk inhibitor p21nd.⁷¹³ Moreover, K8 can directly bind cdk2 complexed to cyclins A and E, and this interaction leads to impaired kinase activity. Interestingly, K8 can be phosphorylated by cdk2⁵⁴⁰ as well as KSHV ORF36, a viral protein kinase.³⁰⁰ Curiously, K8 binds and basally activates the IFN- β promoter, thereby preventing IRF3 binding to the promoter and further IFN- β activation upon Sendai virus infection.³⁷⁶ Additionally, K8 also prevents the activation of IFN- α responsive genes (e.g., 2',5'-OAS) and interferon-sensitive gene (ISG) 15.³⁷⁵

Finally, K8 also plays important roles in viral lytic replication, as it is thought to bind the lytic replication origins of KSHV. These roles will be discussed later in the Lytic Viral Replication section.

Delayed-Early Gene Expression

KSHV proteins belonging to the DE class are genes whose transcription is sensitive to the effects of cycloheximide, because their expression depends on the transactivation of their promoters by IE proteins. However, their expression is independent of viral DNA synthesis inhibitors. Many DE proteins (e.g., DNA polymerase, thymidine kinase, ribonucleotide reductase) have enzymatic functions or serve as accessory proteins (single-stranded DNA binding protein, polymerase processivity factor, etc). The DE proteins prepare the infected cell for viral DNA replication. Other DE proteins are involved in immune evasion (K3/MIR1, K5/MIR2, and K14), host shutoff (ORF37/SOX), nuclear-cytoplasmic transport of viral RNAs (ORF57), or modulation of signal transduction (vGPCR, K1, K15). At least two noncoding RNAs have been identified as DE transcripts: the PAN RNA^{148,642,735,736} and a small transcript originating from one lytic replication origin.⁶⁸⁷ Please note that the term *delayed-early* is borrowed from the alpha herpesvirus literature and may not be as strictly applicable to the various environments that trigger KSHV reactivation. In most cases, the time delay is minimal.

ORF57/MTA

ORF57, also known as MTA, is a posttranscriptional regulator and a homolog of HSV ICP27 and EBV ORF57/MTA proteins. HSV ICP27 promotes the nuclear-cytoplasmic transport of unspliced mRNAs, inhibits RNA splicing, and modulates late mRNA polyadenylation.⁵⁸³ ORF57 moves between the nucleus and cytoplasm⁴⁵ and can also enable the cytosolic accumulation of unspliced mRNAs.^{264,332}

ORF57 interacts with Aly/REF, an export factor, to promote nuclear mRNA export.⁴³¹ ORF57 binds to intronless viral mRNAs and functions to recruit the human TREX (hTREX) complex (through interactions with the export adapter protein Aly), but not the exon-junction complex

(EJC), and assemble a viral ribonucleoprotein particle known as vRNP.⁶⁹ Aly subsequently binds the DEAD-box protein UAP56, which recruits the remaining hTREX components to the complex.⁶⁹ It has also been shown that ORF57 associates with PYM, a protein that recruits the 48S preinitiation complex to newly exported mRNAs through binding EJC. The ORF57-PYM interaction allows this complex to associate with intronless KSHV transcripts to initiate translation of viral mRNAs.⁷⁰

Unlike ICP27, ORF57 does not hinder the expression of intron-containing transcripts,³³² because unlike HSV, many lytic cycle KSHV genes are efficiently spliced (e.g., K8, K14, K15, ORF50, ORF57, the vIRFs, ORF29). During lytic replication, ORF57 partially co-localizes with the cellular splicing machinery in nuclear speckles and assembles into spliceosomal complexes in association with viral pre-mRNAs and essential splicing components. ORF57 binds Sm protein and interacts with small nuclear RNAs. Thus, ORF57 appears to function as a novel factor in the spliceosome-mediated splicing of viral RNA transcripts.⁴³⁰

ORF57 can bind ORF50⁴³¹ and augment ORF50's transactivation function on several viral promoters.^{332,517}

ORF57 can also promote the accumulation of nuclear PAN RNA^{148,332} in an export-independent manner.⁴⁹⁸ It can also bind PAN RNA and protect it from degradation by cellular factors. ORF57 binds PAN RNA directly at an ORF57-responsive element (ORE), thereby protecting it from the cellular RNA decay pathway.⁵⁷⁴ Another mechanism by which ORF57 has been shown to stabilize mRNAs is through inhibition of miRNA modulation of viral transcripts.³¹⁸ The vIL-6 transcript contains an MRE (ORF57/MTA-responsive element) analogous to the ORE reported previously.⁵⁷⁴ Binding of ORF57 to the MREs in vIL-6 stabilized its message and enhanced its translation.³¹⁸ One of the MRE sites was also a binding site for miR-1293, and hence, ORF57 competes with miR-1293 for binding to vIL-6, thereby preventing its RISC-mediated degradation. (ORF57 also interacts with a miR-608 binding site in the cellular human IL-6 transcript and prevents miR-608 repression of this message as well).³¹⁸ Finally, ORF57 interacts directly with the RBM15, thereby stabilizing ORF59 RNA transcript in the cytoplasm.⁴²⁸ A genome-wide analysis of viral RNA targets of ORF57 performed by a UV-cross-linking and immunoprecipitation (CLIP) assay revealed 11 viral transcripts that were targeted by ORF57, including vIL-6.³¹⁸

Additionally, two groups have shown that the disruption of ORF57 in a KSHV BACmid resulted in the lack of expression of several lytic genes, including ORF57, ORF59, K8 α , K8.1, and PAN RNA during the viral lytic cycle and yielded no virion production.^{272,429} Recently, it has been reported that ORF57 is cleaved by caspase-7 during reactivation. The cleaved ORF57 was hampered in aiding the expression of viral lytic genes, suggesting that caspase-7 displays antiviral activity against KSHV lytic proteins.⁴²⁸

Lytic Viral Replication

The DE phase is followed by lytic cycle DNA replication. Similar to the case with other herpesviruses, multisubunit complexes containing the core replication machinery are directed to a *cis*-acting replication origin called *oriLyt* by an ori-specific DNA binding protein. Replication complexes are nuclear substructures where viral replication occurs and these are in proximity to host ND10 domains that are often reorganized as replication progresses.

FIGURE 65.13. The structure of Kaposi's sarcoma-associated herpesvirus lytic replication origins. OriLyt-R and OriLyt-L are superimposed to reveal their commonalities. The *central bar* depicts important common sequence features. *Arrows above the bar* depict the transcripts from this region in OriLyt-L; *arrows below the bar* denote RNAs transcribed in oriLyt-R. Numbers refer to nucleotide sequence of each region. Degree of conservation of each domain between the two origins is indicated by percent homology. (Modified from Wang Y, Li H, Chan MY, et al. Kaposi's sarcoma-associated herpesvirus ori-Lyt-dependent DNA replication: cis-acting requirements for replication and ori-Lyt-associated RNA transcription. *J Virol* 2004;78(16):8615–8629.)

Replication utilizes a rolling circle mechanism, whereby linear genomes are processed and packaged into nascent capsids.

KSHV encodes six catalytic and accessory proteins similar to other herpesviruses, including the viral DNA polymerase (POL, encoded by ORF 9), helicase (HEL, ORF 44), polymerase processivity factor (PPF, ORF 59), primase (PRI, ORF 56), primase-associated factor (PAF, ORF 40/41), and single strand binding protein (SSB, ORF 6). When co-expressed in cells, these proteins form stable multisubunit nuclear structures.⁷¹¹ The KSHV genome contains two oriLyt regions: the left-hand origin (oriLyt L) is situated between ORFs K4.2 and K5, and the right-hand element (oriLyt R) lies between ORFs K12 and 71.^{24,401} These elements promote semiconservative replication that is inhibited by viral DNA polymerase inhibitors (e.g., phosphonoacetic acid). These two approximately 1.7-kb regions share striking sequence homology with one another; the right-hand element seems to be an imperfect inverted repeat of the left-hand element. Each lytic origin is comprised of two subdomains: (a) a 1.1-kb region with multiple AT-rich palindrome sequences, TATA boxes, and transcription factor binding sites and (b) an adjacent region (~600 bp) comprised of multiple GC-rich tandem repeats. Genetic studies have identified four critical elements required for oriLyt L function. These include (a) a high-affinity ORF50 binding site and nearby TATA box, (b) four pairs of C/EBP α sites, (c) an 18-bp AT-rich palindrome, and (d) a 32-bp sequence of unknown function.^{24,687} The RRE and TATA box are components of a promoter that drives expression of a 1.4-kb transcript. Similar features are also present in oriLyt R, where the RRE and TATA element drive expression of kaposin mRNA.⁵⁷³ These similarities are schematized in Figure 65.13, in which oriLyt L and oriLyt R have been superimposed to highlight their commonalities. Among these motifs, C/EBP α binding sites, and RREs function as key *cis*-acting elements.⁶⁸⁹

The oriLyt regions can bind K8 indirectly through the C/EBP α sites.⁴⁰¹ The 18-bp AT-rich palindrome is thought to be the place where initial strand unwinding occurs during the start of DNA replication. ORF50 activates the RRE-containing oriLyt promoter by binding to it and initiating transcription across the GC-rich tandem repeats.⁶⁸⁹ The pre-replication complex, of which ORF50 is a component, is recruited to

oriLyt through the ORF50-RRE and the K8-C/EBP interactions with the oriLyt.⁶⁸⁹

Consistent with its function as a repressor of viral genes, a K8 deleted KSHV BAC displayed an enhanced growth phenotype in terms of virion production and the expression of lytic genes in the context of ORF50/RTA induction.³²³ However, reactivation by chemical induction (TPA and sodium butyrate) yielded no virion production and an aberrant lytic profile compared to wild-type KSHV BAC.³²³ Curiously, immunofluorescence staining revealed that in the absence of K8 there was a disruption of LANA subcellular localization, suggesting that K8 can influence LANA localization.³²³ However, another group showed that a different K8 deleted KSHV BAC displayed no difference in overall viral gene expression during lytic reactivation with TPA in epithelial cells, fibroblasts, and endothelial cells. However, the K8 mutant virus-infected cells displayed lower copy numbers of latent KSHV genomes compared to wild-type KSHV-infected cells. These data suggest two possibilities: (a) K8 may be involved in abortive viral replication (leading to viral genome replication but not virion production), or (b) K8 may be involved in the maintenance of latent viral genomes⁶⁸⁸ through modulation of LANA function, as discussed earlier.^{323,688} The former is likely to be the case because it was recently shown that LANA represses origin-dependent lytic DNA replication in a dose-dependent manner and that this suppression was overcome by increasing amounts of K8.⁵⁶⁹ Additionally, LANA alone was shown to interact with oriLyt by ChIP, implying that the inhibition of lytic replication by LANA was mediated by direct binding.⁵⁶⁹ This suggests a model where LANA interacts with K8 to negatively modulate the switch from latency to lytic replication. Conversely, K8 positively modulates lytic replication by relieving the LANA-mediated suppression of lytic replication. This was also seen in the context of PEL cells where a direct correlation of K8 expression and lytic gene expression was observed.³⁷⁵

Late Gene Expression

As with other herpesviruses, late gene transcription starts subsequent to the onset of DNA replication. The transcription of

many (but not all) late genes is hindered by viral DNA synthesis inhibitors (e.g., phosphonoacetic acid, ganciclovir, foscarnet, cidofovir). Most late genes encode for structural proteins (e.g., capsid and envelope proteins).^{206,306,416,587} Late promoter containing plasmids are not properly transactivated when introduced into reactivated PEL cells, despite the fact that the late promoters in these infected cells are successfully transactivated from the viral genomes undergoing replication.¹²¹ Thus, late templates must either be actively replicating or have undergone a chromatin structure change that depends on viral replication. Consistent with this, when late promoter plasmids are transfected into reactivated PEL, regulation of late genes is partially restored when the reporter gene in question is linked in *cis* to an oriLyt element.⁶⁴⁸

A late gene, ORF19, was found to be regulated by ORF50 through a RBP-J κ site,⁵²⁸ which corroborated earlier findings that gB, another late gene, contained RRE elements in its promoter.⁷⁴³ This suggests that ORF50/RTA can regulate all three transcriptional phases of the lytic program.

FUNCTIONS OF LYTIC VIRAL PROTEINS

Modulation of Antigen Presentation by K3/MIR1 and K5/MIR2

The observation that diseases associated with KSHV infection are substantially more severe in hosts with T-cell impairment (e.g., AIDS) indicates that T cells are critical for the control of viral infection. Immune surveillance and clearance by cytotoxic T (CTL) cells is likely an important selective pressure in driving KSHV evolution with the host; therefore, it is no surprise that KSHV possesses an arsenal of proteins that evade the host's immune system.

The infected cell usually presents antigenic peptides from the virus in complex with class I major histocompatibility complex (MHC I) to CTLs. Two proteins (ORFs K3 and K5) prevent MHC I display.¹⁵¹ K3 and K5 encode for proteins referred to as modulator of immune recognition 1 and 2 (MIR1 and MIR2, respectively); K5/MIR2 down-regulates only human leukocyte antigens (HLA) A and B, whereas K3/MIR1 down-regulates all four HLA allotypes (A, B, C, and E)^{298,634} (Fig. 65.14).

K3 and K5 are transmembrane proteins that resemble each other, suggesting that they may have arisen from duplication of an ancestral gene. Each protein contains an amino-terminal variant RING finger with cysteine and histidine residues that vaguely resemble those found in PHD domain proteins. The zinc finger structure is on the cytosolic face of the membrane.⁵⁸¹ The KSHV MIR proteins show functional similarity to the cellular MARCH protein family. MARCH proteins are transmembrane ubiquitin ligases that ubiquitinate and target cellular glycoproteins for lysosomal destruction³⁵ (Fig. 65.14).

The MIR proteins reside in the endoplasmic reticulum membrane and augment the endocytosis of MHC I chains that reach the cell surface^{151,298} through MIR-mediated ubiquitination.^{285,581} Ubiquitination directed these chains to the endosomes and subsequently the multivesicular body (MVB), a sorting organelle from which the MHC I chains can be targeted for lysosomal degradation.^{285,410,461,581} Interestingly, K3 induces lysine-63-linked polyubiquitination (instead of K48-linked polyubiquitination) of MHC class I chains, which leads to endocytosis and endolysosomal degradation.¹⁸⁹ This

FIGURE 65.14. Ubiquitination and degradation of cell receptors by K3/MIR1 and K5/MIR2. The MIRs are able to induce the ubiquitination and degradation of several of these receptors, including major histocompatibility complex class I, intercellular adhesion molecule 1 (ICAM-1), B7-2, and interferon gamma receptor 1 (IFN- γ R1).

lysine-63-linked polyubiquitination requires the activities of UbcH5b/c- and Ubc13-conjugating enzymes.¹⁸⁹

The MIR RING finger recruits E2 ubiquitin conjugases. K3 and K5 target recognition maps to the transmembrane regions of both effector and target molecules.⁵⁸¹ Subsequently, transfer of the ubiquitin chain to lysines in the cytoplasmic tail can occur. Strikingly, K3/MIR1 can also ubiquitinate cytosolic cysteine residues.⁸⁵

The MIRs can also down-regulate CD1d, a MHC-related protein that presents lipids and glycolipids to classical and non-classical NK T cells, which respond with the release of IFN.⁴⁰⁴ This observation suggests that CD1d-restricted T cells likely play a role in host immunity against KSHV; however, the lipid presentation and antiviral immunity is not well understood. K5/MIR2 (but not K3) also down-regulates ICAM-1 and the co-stimulatory molecule B7-2 (CD86).^{150,297} These two proteins, which are present on antigen presenting cells, can bind and activate CD4-positive T cells. K5-mediated down-regulation of these proteins reduces helper T cell co-stimulation¹⁵⁰ and impairs susceptibility to NK cell cytotoxicity.²⁹⁷ K3 and K5 also down-regulate the interferon gamma receptor 1 (IFN- γ R1),³⁸⁷ thereby preventing it from binding IFN- γ released from activated T and NK cells. KSHV K5 reduces cell surface expression of the NKG2D ligands MHC class I-related chain A (MICA), MICB, and activation-induced C-type lectin (AICL), which is a ligand for NKP80. K5-mediated ubiquitination directs

internalization but not degradation of MICA, resulting in a decrease in NK cell-mediated killing.⁶⁴⁹

Although K3 and K5 appear to be functionally homologous in most cases, there are instances when K5 appears to encode additional functions not performed by K3. For instance, unlike K3, which induces ubiquitin-dependent endocytosis and degradation, K5 can induce the down-regulation of its targets through multiple pathways, including endocytosis-dependent and -independent, as well as ubiquitination-dependent and -independent pathways.⁴⁶² K5 induced the degradation of non-classical MHC I HFE via a polyubiquitination-mediated ESCRT1/TSG101-dependent pathway.⁵⁶⁶ A proteomic screen performed with K5 revealed that it also targets bone marrow stromal antigen 2 (BST-2, CD316), also known as tetherin, activated leukocyte cell adhesion molecule (ALCAM, CD166) and syntaxin-4.³⁶

Independent of its role in immune modulation, K5 has also been implicated in vascular permeability during lytic infection by targeting a junctional endothelial protein—vascular endothelial (VE)-cadherin for ubiquitin-mediated degradation, thereby preventing endothelial cell adhesion. α -, β -, and γ -catenins were also targeted for proteosomal destruction.⁴³⁶ Additionally, in monocytes, K5 expression increased aerobic glycolysis and lactate production in monocytes through activation of receptor tyrosine kinase receptors such as Flt-3 and PDGF- β .³²¹ These signaling and metabolic changes mediated by K5 imply that it potentially plays a role in KSHV-associated oncogenesis. However, because K5 is a lytic protein, its ability to play a role in oncogenesis has certain limitations, which are discussed in the KSHV pathogenesis section later in this chapter.

Although K5 is a lytic protein and only expressed in 1% to 5% of spontaneously reactivated PEL, *de novo* infection of naive cells resulted in down-modulation of the K5 targets in most cells. The down-regulation of MHC I and ICAM-1 correlated with intracellular KSHV load, indicating that low levels of K5 is sufficient for global down-regulation of these markers during primary KSHV infection.^{6,651}

Interferon Evasion by Viral Interferon Regulatory Factors

Several KSHV lytic proteins are involved in preventing the activation and function of type I IFNs that are produced in response to infection. As described earlier, IFNs are induced by PAMPs, which are recognized by innate immune sensors such as TLRs and RIG-I-like receptors (RLRs; e.g., RIG-I and MDA-5). Activation of TLRs and RLRs leads to the activation of cellular IRFs (e.g., IRF3 and IRF7) depending on which TLR is stimulated, type I IFN (IFN- α and IFN- β), and inflammatory cytokines. IFN- α/β released from the cell can bind to IFN- α and IFN- β receptors present on surrounding cells. This signal is transduced to the nucleus, thereby stimulating the transcription of multiple ISGs, which include known antiviral effectors (e.g., OAS, Mx, and PKR) as well as the IRFs themselves.

IFN- α/β binding to IFN receptor leads to the phosphorylation and activation of STAT1 and STAT2. The activated STATs then bind to IRF9 (p48) and relocate to the nucleus to induce transcription from ISG promoters. Both the IFN- α/β and the ISG promoters contain IRF binding sites for many cellular IRFs.

The KSHV genome encodes four different homologs of cellular IRFs from a single locus, which suggests that they arose from an ancestral gene through gene duplication followed by divergence. vIRF-1, -2, -3, and -4 were named based on their order of discovery and not by their homology to a particular cellular IRF. vIRF-3 is a latent gene, as discussed previously.

The remaining vIRFs (vIRF-1, -2, and -4) are mostly expressed during the lytic cycle. Although vIRF-1 is a lytic gene,^{81,747} it was found to be transcribed in latently infected KS cells as well.^{132,181} vIRF-1, -2, and -3 do not share the DNA binding domain of the cellular IRFs and hence do not bind to IRF binding sites in ISG and type I IFN promoters. However, these three vIRFs hinder the function of cellular IRFs, thereby suppressing IFN production (Fig. 65.15). Moreover, the vIRFs have also been shown to differentially modulate TLR3-mediated activation of IFN.^{303a} Please note that vIRF-4 has not yet been shown to affect IFN signaling.

vIRF-1 (encoded by ORF K9) is the most well studied vIRF and can inhibit IFN production in response to Sendai virus infection.^{226,747} vIRF-1 dimerizes with cellular IRF1 and IRF3, which prevents the cellular IRFs from transactivating the IFN promoters, although DNA binding does not appear to be affected. Inhibition of IRF function is thought to occur through vIRF-1's ability to bind and sequester co-activator CBP/p300 from cellular IRFs thereby inhibiting its HAT activity.^{81,385,402} vIRF-1's ability to prevent apoptosis and evade immune responses is likely to greatly contribute to KSHV pathogenesis.

Studies have also demonstrated the ability of vIRF-2 to impair IFN-dependent transcription. In the context of type I IFN, vIRF-2 inhibited ISG56 activation,²¹⁸ cellular IRF1- and IRF3-mediated transcriptional activation,^{81,218} IFN- β promoter activity in response to double-stranded RNA and IRF3 transfection,²¹ and ISRE transactivation mediated by the IFN- γ family members IL-28A or IL-29.²¹⁸ vIRF-2 was unable to inhibit IRF7-mediated transactivation of ISG promoters, as well as the IFN- γ promoter (pGAS) in response to IFN- γ treatment.²¹⁸

Similar to vIRF-1 and vIRF-2, vIRF-3 has been shown to inhibit transactivation of the IFN- $\alpha 4$ and IFN- $\alpha 6$ promoter upon Sendai virus infection as well as in the presence of exogenous IRF3 and IRF7.^{313,419} vIRF-3 could also inhibit IFN- γ -mediated activation of the GAS promoter.⁴¹⁷ Furthermore, vIRF-3 expression led to the reduction of endogenous IFN- $\alpha 1$, - $\alpha 4$, and - $\alpha 6$ mRNA levels upon Sendai infection³¹³ and the production of IFN following infection with Newcastle disease virus.⁴¹⁹

In addition to their ability to inhibit IFN, the vIRFs have also been shown to prevent apoptosis. vIRF-1 was shown to relocalize the proapoptotic protein Bim, a negative regulator of KSHV replication, to the nucleus.¹⁴⁰ This nuclear sequestration of Bim prevents apoptosis during viral replication, thereby leading to increased viral production during the lytic phase.¹⁴⁰ Furthermore, vIRF-1 expression in mouse fibroblasts can induce cellular transformation, which is probably due to the fact that vIRF-1 can also bind p53 and inhibit apoptosis.^{226,488} vIRF-1 co-precipitates with p53 and inhibits p53-driven transcription and targets (e.g., p21 and Bax).^{488,598} Expression of vIRF-1 can also lead to a decrease in total p53 levels owing to vIRF-1 directed ubiquitination and degradation of p53.⁶⁰⁴ This activity required the p53 E3

FIGURE 65.15. Innate immune evasion by Kaposi's sarcoma-associated herpesvirus (KSHV) viral interferon regulatory factors (vIRFs), open reading frame (ORF) 50/replication and transcription factor (RTA), ORF45, and ORF63. KSHV entry triggers activation of toll-like receptor (TLR) 3 in monocytes and TLR4 in endothelial cells. Furthermore, binding of latently infected B cells by TLR7/8 agonists leads to reactivation of KSHV from latency. The vIRFs block interferon activation by host cells. ORF50/RTA targets IRF7 for degradation, whereas ORF45 inhibits IRF7 function. ORF63 inhibits activation of the NLRP1 and NLRP3 innate immune sensors.

ligase MDM2. Inhibition of p53-mediated apoptosis may be a mechanism through which KSHV is able to establish latency. In addition to vIRF-1, vIRF-3 and vIRF-4 also interfere with p53 signaling. Like vIRF-1, vIRF-3 was shown to interact with p53 *in vitro* and reduce p53 reporter activity.⁵⁶⁷ vIRF-3 also decreased apoptosis and activation of caspase-8 mediated by p53.⁵⁶⁷ Finally, vIRF-4 interferes with the p53 pathway by interacting with MDM2 to increase MDM2 protein levels³⁷² through the inhibition of MDM2 autoubiquitination and prevention of MDM2 proteasomal degradation.³⁷² Interestingly, both vIRF-1 and vIRF-4 induce MDM2-mediated p53 degradation, but through dif-

ferent mechanisms. A detailed review of the function of the four vIRFs is provided elsewhere.³⁰³

Two other KSHV proteins, which are not homologs of cellular IRFs, can also block IRF action. ORF50 was shown to induce IRF7 degradation as described earlier. Additionally, the IE protein ORF45 can interact with IRF7 and prevent its phosphorylation and nuclear translocation⁷⁴⁰ (Fig. 65.15). ORF45 interacts with an inhibitory domain in IRF7,⁵⁹⁰ which keeps IRF7 in a closed inhibitory state. Because ORF45 is a tegument protein,⁴⁰⁶ in theory it should be able to hinder type I IFN activation pretty soon after viral infection. A KSHV recombinant virus deleted for ORF45 exhibited lower viral

replicative capacity compared to wild-type virus.^{741,742} ORF45 has also been shown to interact with p90 ribosomal S6 kinases (RSKs), RSK1 and RSK2, and strongly stimulates their kinase activities leading to ERK activation.^{353,354} ORF45 interacts with seven in absentia homolog (SIAH), an E3 ubiquitin ligase,¹ and KIF3A, a kinesin-2 motor protein that transports cargo along microtubules to the cell membrane. ORF45 principally mediated the docking of entire viral capsid-tegument complexes onto the cargo-binding domain of KIF3A.⁵⁹¹

Overall, KSHV encodes a battery of viral proteins dedicated to the ablation of IRF activation, and their function is testimony to the significant role that innate immunity plays in the viral life cycle (see Fig. 65.15).

Modulation of Inflammatory Pathways

In addition to the vIRF proteins, KSHV also encodes for virally encoded CC chemokines: vCCL-1 (formerly known as v-MIP-I, the product of ORF K6), vCCL-2 (vMIP-II, from ORF K4), and vCCL-3 (v-MIP-III, from ORF K4.1).⁵⁰¹ Although chemokines are generally positive mediators of immune and inflammatory responses, the receptor preferences for the KSHV-encoded chemokines are consistent with their function as inhibitors of inflammation in response to viral infection. The CD4 T-cell subset of Th1 cells shape antiviral cytotoxic immune responses by promoting IL-2, TNF- α , and IFN- γ induction, which can activate macrophages and promote the development of CD8+ CTL responses. Th2 cells, on the other hand, promote induction of IL-4, IL-5, IL-6, IL-10, and IL-13 in order to elicit B-cell differentiation and humoral immunity (as well as allergic-type responses). Th2 cells also polarize immunity away from cytotoxic responses regulated by Th1 cells. The chief chemokine receptor on Th1 cells is CCR5, whereas Th2 cells express CCR3, CCR4, and CCR8 receptors. KSHV vCCL-1 signals through CCR8, vCCL-2 signals through CCR8 and CCR3, and vCCL-3 signals through CCR4.^{199,500,635} In summary, the KSHV chemokines activate chemokine receptors that are distributed on Th2 cells. Moreover, vCCL-2 can interact with other chemokine receptors including CCR1, CCR2, CCR5, CXCR1, CXCR2, and CXCR4. However, binding of vCCL-2 to these receptors does not activate signaling but rather inhibits signal transduction by these receptor proteins in the presence of their chemokine ligands. For example, binding of RANTES and MIP-1 α to activate CCR5 is inhibited by low amounts of vCCL-2. Thus, vCCL-2 appears to promote Th2 responses and also inhibit Th1 responses (Fig. 65.16). Consistent with this observation, KS lesions contain more Th2 T cells (CCR3+) than Th1 T cells (CCR5+).⁶⁹³ Moreover, treatment of lymphocytic choriomeningitis virus-infected mice with vCCL-2 inhibits CD8 T-cell migration into the lesion and impairs local inflammation. vCCL-2 treatment also hinders CTL-mediated rejection of experimental corneal and cardiac allografts.^{165,535}

Apart from their anti-inflammatory properties, the viral chemokines can also promote angiogenic responses and induce VEGF from PEL.^{57,406} Additionally, the vCCLs can promote cell survival in an autocrine and paracrine manner—the vCCLs inhibit the expression of the proapoptotic protein Bim during KSHV lytic replication.¹³⁹

KSHV K14 encodes a glycoprotein of the immunoglobulin (Ig) superfamily that resembles cellular CD200 (also known as OX2). CD200 is expressed on many cell types (B, T, and

FIGURE 65.16. Kaposi's sarcoma–associated herpesvirus encoded viral chemokines (vCCLs) block Th1 responses and augment Th2 responses. These viral chemokines have also been shown to activate angiogenic pathways.

endothelial cells), and its receptor (CD200R) is located on cells of the myeloid lineage (basophils, neutrophils, and monocyte-macrophages). Cellular CD200 is a negative regulator of inflammation and myeloid cells, and CD200 knockout mice have an increase in monocytes and macrophages, as well as macrophage and microglial activation, and increased susceptibility to experimentally induced autoimmune disease.²⁸⁷ Soluble recombinant KSHV K14/vOX2 protein binds to CD200R.²¹⁴ There is some discrepancy in the literature regarding the inflammatory nature of K14,¹⁴² whereas other studies found that K14/vOX2 suppresses markers of myeloid activation, including suppression of TNF- α production by activated macrophages, decreased MCP-1 and IL-8 production by a monocytic cell line, reduced oxidative burst in primary neutrophils triggered with a phagocytic stimulus, and a blunted release of histamine from activated basophils.^{214,565} One study suggests that the function of K14 may depend on the cell type and activation state. In human primary monocyte-derived macrophages, K14/vOX2 induced proinflammatory cytokines and displayed higher phagocytic activity with respect to mock cells. However, the presence of K14 in MDMs undergoing IFN- γ activation led to a down-modulation of cytokine production and phagocytic activity.⁵⁷⁸

A recent report showed that KSHV encoded a viral protein, ORF63, with homology to the nucleotide-binding and

oligomerization, leucine-rich repeat (NLR) family of proteins.²⁴⁹ NLRs mediate antiviral immune responses to many different invading viruses. Some NLRs form a large molecular structure called an *inflammasome* upon activation. The inflammasome contains oligomerized NLRs, apoptotic-associated speck-like protein (ASC), and procaspase-1. Activation of this complex results in the autocatalytic processing of procaspase-1 to caspase-1. Activated caspase-1 subsequently cleaves the precursors of proinflammatory cytokines pro-IL-1 β and pro-IL-18 to their biologically active forms IL-1 β and IL-18, respectively.³¹⁹ ORF63 is a tegument protein and hence is present in the incoming virion. ORF63 could bind and inhibit the association of the NLR family member NLRP1 with procaspase-1 and prevent the processing of procaspase-1 and subsequent processing of pro-IL-1 β and pro-IL-18²⁴⁹ (see Fig. 65.15). ORF63 inhibition of NLRP1 was found to be important during reactivation from latency and primary infection.²⁴⁹

Transmembrane Signaling Proteins

K15

The coding regions adjacent to the KSHV TRs encode two signaling proteins: K1 and K15. K1 (described earlier) is located at the left-hand side of the genome, and at the right end of the genome lies ORF K15, which encodes for another transmembrane signaling protein. Expression of K15 is highly increased during lytic growth, and its expression during latency has been controversial. It was initially named latency-associated membrane protein (LAMP)²⁴¹ and is expressed at low levels during latency⁶⁰¹ (Dr. Thomas Schulz, personal communication). K15 mRNAs originate from alternatively spliced transcripts that include eight or fewer exons encoding up to 12 transmembrane domains, and a cytosolic tail.^{138,241} All spliced variants encode the carboxy-terminal tail linked to varying numbers of transmembrane domains. The full-length proteins contains eight exons (12 transmembrane). All K15 protein variants are found on intracellular membranes and the plasma membrane. A subset of K15 in the plasma membrane is associated with lipid rafts.⁷³ The K15 cytoplasmic region can be tyrosine phosphorylated and appears to inhibit BCR signal transduction.¹³⁸ The cytosolic tail contains a SH2 binding motif (YEEVL), and the Y is phosphorylated *in vivo* by the Src family of kinases. The cytoplasmic domain contains an SH3-binding region, and another motif (YASIL) represents an endocytosis signal and a potential site of tyrosine phosphorylation.

The cytoplasmic tail also contains a TRAF binding site (ATQPTDD). K15 binds TRAFs 1, 2, and 3 and constitutively activates NF- κ B, JNK and ERK, and MAP kinase signaling pathways, leading to up-regulation of transcription factor AP-1.^{73,241} In this manner, K15 is capable of inducing the expression of an array of cytokines and chemokines, including IL-8, IL-6, CCL20, CCL2, CXCL3, and IL-1 α/β , Dscr1, and Cox-2⁷⁴ (see Fig. 65.9).

Activation of MAP kinase signaling might be important for mediating lytic replication, because MAP kinase activation is necessary for full lytic induction and reactivation from latency.^{145,518,599,719} K15 also interacts with the protein HAX-1, an antiapoptotic factor, suggesting another mechanism (besides NF- κ B induction) by which K15 contributes to enhanced cell survival.⁶⁰¹ K15 can interact with Lyn and Hck kinases.⁵³⁴ Thus, K15 appears to contribute to KSHV

pathogenesis through the up-regulation of multiple inflammatory cytokines and the activation of multiple signaling pathways (see Fig. 65.9).

It is interesting to note that K1 and K15 occupy analogous positions in the KSHV genome to those occupied by LMP1 and LMP2A in the EBV genome (see Fig. 65.3). However, it appears that certain cytoplasmic motifs and functions may have been interchanged between these viral proteins. For example, although K1 is in the same genomic location as EBV LMP1, it contains an ITAM similar to EBV LMP2A and not EBV LMP1. On the other hand, K15 is similar to EBV LMP2A and can inhibit BCR signaling.^{138,466} Thus, generally speaking, K1 and K15 perform similar functions in concert to those of LMP1 and LMP2A combined. However, although LMP1 and LMP2A are expressed in some EBV latency programs, distinct latency programs for KSHV have not been described.

Viral G-protein Coupled Receptor

In addition to K1 and K15, discussed earlier, KSHV encodes a third transmembrane signaling molecule encoded by ORF74, a vGPCR. It is a member of the family of seven transmembrane G protein coupled chemokine receptors.¹¹¹ Expression of this protein depends on ORF50 and is restricted to the lytic cycle.^{137,333} The protein displays constitutive signaling activity in the absence of ligand, although its activity can be stimulated further by chemokines (e.g., GRO- α) and down-regulated by chemokines (e.g., CXCL10/IP10).^{22,234} The resulting signaling activates the PI3K/Akt/mTOR and p38 pathways,^{94,473,617,619,620,621} and the NF- κ B activity,^{439,595} angiogenesis, and cell proliferation^{26,27,274} (see Fig. 65.9). Indeed, vGPCR-deleted recombinant viruses are impaired for viral replication, and vGPCR's function in lytic replication depends on its ability to signal through G α_q and activate MAP kinase signaling.⁵⁸²

Owing to this potent signaling activity, vGPCR activates expression of many host genes.⁵⁴¹ Among these are Rac1⁴⁷⁵ and VEGF^{27,621} a critical mediator of vascular permeability and angiogenesis. Further, expression of vGPCR in mice in several different cell lineages generates focal angioproliferative lesions that have some features in common with KS.^{263,472,722} A notable commonality among two of the models where expression was evaluated at the cellular level is that vGPCR was expressed only in a small proportion of the cells in the lesions, which has led to the belief that in KS lesions, expression by a few lytic cells can induce pathology through paracrine mechanisms.¹⁰⁹ Because vGPCR can be linked to both proliferation and angiogenesis, it may be a key element in KS pathogenesis.^{26,621} Additionally, siRNA suppression of vGPCR in the context of the whole viral genome also inhibited angiogenesis and tumorigenicity.⁴⁸¹ Interestingly, transgenic mice that express the constitutively active form of the small GTPase Rac1 develop KS-like lesions.⁴²⁶ Transcription profiling showed many consistencies between KS tumors and the Rac1 tumors. The tumorigenesis seen in the Rac1 model depended on activation of Akt signaling, ROS-induced proliferation, and hypoxia-inducible factor 1- α (HIF-1 α). Furthermore, inhibitors of ROS reduced tumorigenesis in this model.⁴²⁶ The contribution of lytic genes to oncogenesis is further discussed in the Kaposi's Sarcoma-associated Herpesvirus Pathogenesis section.

Host Shutoff

Many previous attempts to examine the effects of lytic replication on host gene expression in KSHV were hindered by the low frequency of lytic replication in chemically induced PEL lines. However, systems now exist where lytic reactivation is seen in most cultured cells.^{483,671} This is typically performed by infecting cultured cells with KSHV at a high MOI, after which cells are allowed to establish latency; these cells are subsequently superinfected at a high MOI using baculoviral or adenoviral vectors expressing ORF50. This induces the lytic cycle in most cells in culture. Under these conditions, most lytically infected cells display some degree of inhibition of host gene expression 10 to 12 hours postinfection.²⁴⁰ The principal block appears to be at the level of host mRNA accumulation.^{239,240} This phenomenon can be attributed to a single protein encoded by ORF37.

KSHV ORF37 encodes for a DE protein called *shutoff exonuclease* (SOX). Homologs of SOX exist in other herpesviruses as well. In HSV, the SOX homolog is not involved in host shutoff (which instead is mediated by ICP27 and VHS). The KSHV SOX protein retains DNA exonuclease activity similar to its HSV counterpart; however, this function can be genetically separated from its function in host RNA shutoff.²³⁹ Importantly, a small subset of host mRNAs escape SOX-mediated turnover.²⁴⁰ Cellular IL-6 message is one of these transcripts. Mapping studies have shown that the 3' UTR of IL-6 mRNA contains elements that allow it to escape from SOX-induced degradation. The length of polyadenylated tails is now emerging as a distinct marker of mRNA fate, and differences from the canonical length led to either degradation or nuclear retention. KSHV SOX stimulates RNA turnover through polyadenylation-linked mRNA turnover.³⁷⁴ Inhibition of poly(A) tail formation blocks ORF37/SOX activity, and transcripts in SOX-expressing cells exhibit extended poly(A) polymerase II generated poly(A) tails. The poly(A) binding proteins (PABPs) were also shown to be essential for SOX function.³⁷⁴ Exactly how selectivity for host mRNAs is achieved by SOX, while viral transcripts are spared, remains to be elucidated.

KAPOSI'S SARCOMA-ASSOCIATED HERPESVIRUS PATHOGENESIS

In this section, we review the cellular and molecular mechanisms that underlie KSHV's relationship with its associated cancers.

Molecular Pathogenesis of Kaposi's Sarcoma

Histologically, KS tumors are highly complex, unlike most classical cancers that arise as a clonal outgrowth of a single cell type.^{559,560} This makes KS different from traditional forms of cancer, where the malignant cell is of a clear, distinct type. In KS, the chief proliferating cell is called the *spindle cell*, which is named after its spindle-like shape. As mentioned earlier, the spindle cells are of endothelial lineage, because they express many markers of endothelial origin, including factor XIII, CD31, CD34, CD36, En-4, and PAL-E.^{18,203,204,284,559} However, some spindle cells lack the presence of factor VIII, which is a marker of differentiated vascular endothelium. Spindle

cells also display heterogeneity in marker expression.⁵⁵⁹ For example, some spindle cells in KS biopsies stain for factor VIII, whereas other cells stain for smooth muscle α -actin. This has prompted suspicion that spindle cells might arise from mesenchymal precursors that form vascular and smooth muscle cells.⁴⁰⁹ Another possibility is that the cells arise from lymphatic endothelium.⁴¹ This hypothesis is concordant with the observation that molecular markers of lymphatic endothelium (e.g., VEGF-C, VEGF-R3, LYVE-1, and podoplanin) are also regularly expressed by KS spindle cells.^{437,615,696}

Gene expression profiling studies of infected endothelial cells^{103,273,288,677} found that latent viral infection reprograms expression of endothelial markers, inducing the vascular endothelium to express lymphatic markers such as PROX1, whereas the lymphatic endothelium displays a more vascular-like profile. These studies indicate that examination of just one endothelial marker does not provide clues to the lineage of the infected cells. On the basis of miRNA profiling, it has been shown that there exist multiple distinct stages of endothelial cell reprogramming by KSHV, which is most significantly associated with the down-regulation of mir-221.⁵⁰⁴ In view of the stage-wise reprogramming, which endothelial cell type represents the actual progenitor of the KS spindle cell is still unclear; it is still possible that multiple types of endothelial cells could give rise to the KS spindle cell following viral infection. The resultant KS spindle cell may be shaped as much by the viral infection as by the microenvironment. Recently, KSHV infection of endothelial cells has also been shown to induce transcriptional reprogramming of lymphatic endothelial cells to mesenchymal cells through endothelial-to-mesenchymal transition (EndMT).^{135c}

KSHV-infected endothelial cells up-regulate several signal transduction pathways, including the PI3K/Akt/mTOR pathway and JAK2/STAT3 pathway.^{478,678} STAT3 activation was mediated by gp130 receptor, a common receptor of the IL-6 cytokine family. Both Akt and STAT3 were necessary for KSHV-induced lymphatic reprogramming of endothelial cells.⁴⁷⁸

In addition to spindle cells, KS lesions also contain infiltrating T cells, B cells, monocytes, and aberrant slit-like neovascular spaces. The neovascular spaces are lined with both infected and uninfected endothelial cells.¹⁹¹ They do not contain pericyte or smooth muscle cells and are very susceptible to leakage and rupture. Because of these features, KS lesions often exhibit hemorrhage, with erythrophagocytosis by inflammatory cells in the interstitial spaces. The KSHV-infected endothelial cells display increased vascular permeability. Lytic infection is associated with VE-cadherin degradation^{194,436,545} attributed to the actions of K5 and vGPCR, whereas latent infection is associated with increased Rac1 activation and ROS generation leading to disruption of endothelial junctions owing to the phosphorylation of VE-cadherin.²⁶¹ Thus, the histologic appearance of KS probably results from at least four different processes: proliferation, inflammation, reprogramming, and angiogenesis. These processes are intertwined but distinguishable.

KS can occur in various sites. It is frequently localized to the skin, and in the sporadic classical form, it may be restricted to the lower extremities. In the skin, the dermis is involved, with sparing of the overlying epidermis.⁵²¹ Although progression is not quite linear, and patients may present with lesions in all stages, in general terms, cutaneous KS is thought to begin as a *patch* lesion, with histologically demonstrable spindle cells

that are not necessarily the predominant cell type; inflammatory cells and neovascular elements are also abundant at this stage. The lesion may progress through a plaque-like stage to the *nodular* stage, with the proportion of spindle cells becoming progressively larger as the lesion progresses. By the nodular stage, spindle cells fill up most of the lesion. The spindle cell progressively dominates during the course of KS and is therefore considered to be the key tumor cell.

In immunocompetent adults, the classical form is frequently indolent, and afflicted individuals have long survival times. However, in immunocompromised hosts, KS is highly aggressive, with widespread involvement of lymphoreticular structures and multiple organs such as the gastrointestinal tract, the lung, and skin. Pulmonary KS has a grave prognosis because it is often accompanied by death from respiratory failure. Analysis of KS spindle cell clonality has revealed that KS lesions are either oligo- or polyclonal.^{169,192,238,314} Although clonality is observed in some KS lesions,⁵⁴⁸ the lesion is generally thought to be oligo- or polyclonal throughout much of its development, including progression to macroscopically visible KS. One striking feature is how frequently the individual lesions in a KS patient appear to have arisen independently. This is different than that observed in most classical cancers and underscores the uniqueness of KS. This scenario is reminiscent of that seen with EBV-driven post-transplant lymphoproliferative disorders, where lesions can be polyclonal, showing a possible progression to monoclonality, and when multiple, they may be of different clonal origin in a single patient.^{112,337} Cellular pre-miRNA profiling of KSHV-infected endothelial cells and KS tumors revealed that as cells infected with KSHV transitioned from immortalization to fully tumorigenic, there was a loss of mir-221 expression and a gain of mir-15 expression.⁵⁰⁴ Expression of mir-140 and the KSHV viral miRNAs increased proportionally with the degree of transformation.⁵⁰⁴ Additionally, down-regulation of multiple tumor suppressor miRNAs was observed in KS and PEL.⁵⁰⁶ Because the tumor suppressor proteins themselves are, for the most part not mutated in these tumors, regulation of their expression in KS and PEL highlights a novel, alternative mechanism of transformation.⁵⁰⁶

KS spindle cells only exhibit a few of the hallmarks of transformation. KS cells highly depend on growth factors and cytokines when cultured *in vitro*.^{203,204,465} KS cells also do not display genetic instability, although this may reflect the nature of viral cancers, which tend to show less genetic instability (e.g., p53 mutations) in general.¹⁵⁶ KS spindle cells are diploid and do not display microsatellite instability, although certain advanced AIDS-KS tumors can display these characteristics.⁴² The KS spindle cells depend on cytokines and growth factors (perhaps from infiltrating inflammatory cells) in their microenvironment for their proliferation; however, they themselves can generate angiogenic and proinflammatory factors to recruit additional blood vessels to the site of the infected lesion. Thus, KS highly depends on its microenvironment for growth and survival.^{203,204}

Role of Hypoxia in Kaposi's Sarcoma Biology

One descriptive observation involving KS was that it often (but not always) develops in the lower extremities, such as the feet, where tissue may be less oxygenated. A seminal finding revealed

that low oxygen conditions (i.e., hypoxia) leads to the reactivation of KSHV replication from latently infected PEL.¹⁶² Hypoxia augmented vIL-6 secretion, as did several compounds that increase the levels of HIF-1. Hypoxia also increased expression of the viral kinase KSHV ORF36 and the thymidine kinase encoded by ORF21.¹⁶³ HIF is a master regulator of angiogenesis and is activated posttranscriptionally by hypoxia, leading to increased protein stability of HIF-1 α and/or HIF-2 α . Consistent with this hypothesis, the KSHV genome contains several hypoxia response elements (HREs).²⁷⁵ The ORF50/Rta and the ORF34 promoters contain HREs, which under hypoxic conditions are activated by HIF-1 α and/or HIF-2 α .²⁷⁵ As mentioned earlier, XBP-1s can reactivate KSHV from latency, and it has been reported that hypoxia also induces active XBP-1s.¹⁵⁹

Additionally, in the context of primary KSHV infection, there is an increase in HIF activity under normoxic conditions.¹⁰⁴ Both HIF-1 α and HIF-2 α proteins are elevated in KSHV-infected cells.¹⁰⁴

Finally, KSHV infection of B and endothelial cells has also been shown to increase aerobic glycolysis leading to lactate secretion, i.e. the Warburg effect, and to augment fatty acid synthesis (FAS). Inhibitors of glycolysis and FAS enhance cell death of KSHV-infected cells.^{49a,171,171a}

Molecular Pathogenesis of Primary Effusion Lymphoma and Multicentric Castleman's Disease

Gene expression profiling demonstrated that PEL display a distinct profile from all other non-Hodgkin's lymphoma (NHL) that is related neither to GC nor to memory B cells.³³⁴ The mRNA profile of PEL was defined as plasmablastic because it showed features of both immunoblasts (similar to EBV-transformed lymphoblastoid cells) and plasma cells (similar to multiple myeloma cells).³³⁴ Another group reported that the stage of B-cell development represented by PEL closely resembles that of malignant plasma cells.³⁰⁷ The unfolded protein response (UPR) is partially activated in PEL (e.g. XBP-1), and genes overexpressed in PEL include those involved in inflammation, cell adhesion, and invasion.³⁰⁷ KSHV-infected PEL have also been found to up-regulate the PI3K/Akt/mTOR signaling pathway,^{49,610,657} as well as higher levels of B-Raf and angiogenic VEGF-A as compared to other lymphoma subtypes. MEK inhibition reduced VEGF-A expression in PEL.⁹ Genome-wide comparative genome hybridization (CGH) found consistent deletions in fragile sites that encode the FHIT and WWOX tumor suppressor genes.⁵⁷⁰ In terms of viral gene expression, most of the PEL cells express latent genes (e.g., LANA, vCyclin, vFLIP, vIRF-3).^{206,489} However, between 1% and 5% of PEL spontaneously reactivate in culture and display lytic gene expression.

MCD is associated with both latent and lytic infection. In MCD, latent (LANA) and lytic (ORF59, K8, and K10) viral proteins are expressed.^{322,521} One protein that is constitutively expressed in a significant proportion of KSHV-infected cells in MCD is vIL-6, which as described earlier is expressed during latency and is highly up-regulated during lytic infection.^{114,322,511,521} It is thought that expression of lytic proteins contributes extensively to the pathobiology of MCD.

Kaposi's Sarcoma—Associated Herpesvirus Gene Expression in Kaposi's Sarcoma and Primary Effusion Lymphoma

KSHV viral DNA is present in all KS tumors, regardless of type of KS or disease stage. As mentioned earlier, KSHV specifically targets the spindle cell compartment within the tumor.^{59,191,629} However, when passaged *in vitro*, the spindle cells generally lose the viral genome. It has been reported that monocytes in the lesion can also be infected by KSHV^{55,514} as well as some epithelial cells.^{211,521,558,629} *In situ* hybridization for latent mRNA transcripts suggest that most KS spindle cells are latently infected; yet, a small subpopulation (<1%–2%) expresses markers of lytic infection.^{179,191,322,629,636} With the exception of vIRF-3, all latent genes expressed in PEL are also found as latent genes in KS.⁵⁶⁷

Similar to EBV, it is thought that the latency program drives tumorigenesis. Early (patch) lesions of KS have only a small proportion of cells. Fewer than 10% of spindle-like cells are LANA-positive, whereas in more progressed lesions, a variable but higher proportion of spindle cells are latently infected.^{191,629} A study that included quantification of the LANA-positive cells in KS lesion tissues using automated image analysis showed that the percentage of LANA-positive cells ranged from 0.49% to 15% of the total number of cells in KS lesions.³⁴¹ This study was done in the context of a clinical trial of KS patients in the United States who were receiving antiretroviral therapy, raising the possibility that earlier studies, which reported the presence of KSHV in most spindle cells in advanced lesions, were seeing a larger proportion of infected cells in patients with more severe immunodeficiency. The *in vitro* properties of the latent proteins (e.g., the inhibition of p53 and Rb by LANA, the induction of NF- κ B by vFLIP, the stimulation of cdk6 by vCyclin, and the up-regulation of β -catenin by LANA) are commensurate with transformation, growth advantage, and survival. However, it is important to note that these functions were identified in experiments involving overexpression of individual viral proteins. When most transformed cell lines are infected with KSHV, the resulting latent infection does not greatly impact their biology.^{39,357,670} However, when KSHV infects primary (or immortalized) human endothelial cells, the virus replicates for the first few days (usually with significant CPE) and spreads through the monolayer.^{143,227} Over the next 7 to 10 days postinfection, lytic replication subsides and most cells become latently infected. The resulting LANA-positive cells exhibit a change in morphology (i.e., elongation to a spindle morphology) similar to that seen in KS tumors *in vivo*. In most cases, the primary cells are not immortalized by KSHV,^{143,227,647} although some experimental conditions have resulted in a marked delay of senescence.²¹⁰ Similarly, most KSHV-positive primary endothelial cells cannot form tumors in nude mice or grow in soft agar. However, An et al¹⁵ did isolate a KSHV-infected immortalized endothelial line (TIVE) in which KSHV-infected cells were tumorigenic and grew out many weeks following infection. These KSHV-infected TIVE cells do give rise to tumors in nude mice.¹⁵ However, this cell line appears to represent the exception to the rule rather than the norm (R. Renne, personal communication).

The above results may simply reflect the paucity of culture conditions to successfully propagate KSHV-infected endothelial cells. Indeed, a similar situation is observed in EBV where epithelial cells like nasopharyngeal carcinoma (NPC) cells lose

the EBV genome during passage in tissue culture.¹⁸² This is despite the fact that EBV-infected B lymphoma cells do not lose the virus during similar passage, as is the analogous situation with KSHV-infected B lymphoma cells. Thus, in contrast to B lymphoproliferative cells, it is generally not possible to establish cell lines from either NPC or KS that retain the EBV and KSHV episomes, respectively, during passage in tissue culture. However, *in vivo*, every KS and NPC tumor cell retains the viral genome.

Early studies showed that KSHV infection of primary B cells *in vitro* is inefficient and, in contrast to EBV, does not lead to immortalization.⁴⁶⁴ Infection efficiency was enhanced when primary B cells were activated and expressed DC-SIGN.⁵⁵⁵ When KSHV DNA was transfected into BJAB B cells, the virus was maintained as an episome and could establish latency with a low level (1%–5%) of underlying spontaneous lytic replication.¹³⁴ The latent viral gene profile was similar to that observed in PEL, and the virus could be reactivated to produce infectious progeny virions.¹³⁴ *In vivo*, it appears that KSHV can infect B cells and *in vitro* infection of primary tonsillar B cells has shown that activated T cells help to promote and stabilize latency^{482,484} and that these infected B cells predominantly express lambda light chain.²⁷⁹

Unprecedented Role for Viral Lytic Proteins in Kaposi's Sarcoma—Associated Herpesvirus Oncogenesis

The latency program has traditionally been associated with tumorigenesis (as is the case with EBV). Hence, it was surprising that independent evidence from clinical studies suggested that both lytic replication and latency play an important role in KS development. In the case of patients with advanced AIDS, the administration of ganciclovir (GCV)—a drug that blocks lytic but not latent KSHV infection—prevented the onset of new KS tumors.⁴⁴⁰ This is a striking result because these patients were infected with HIV and KSHV for many years; the fact that the administration of GCV blocks tumor appearance suggests that viral reactivation may be necessary to support KS development. Further, patients with KS typically display elevated levels of circulating KSHV viral load in the blood.^{89,90,95,200,542} However, treatment with two other antiviral drugs, namely oral valgancyclovir and cidofovir, failed to affect already established KS lesions.^{349,405} One could speculate that dependence of KSHV lytic genes exists during the initial stages of lesion formation. Subsequently, fully tumorigenic spindle cell clones may emerge, in which host cell mutations lead to independence of KSHV lytic proteins.

How Might Lytic Replication Contribute to Kaposi's Sarcoma Tumor Development?

The lytic and latent phases of the viral life cycle go hand in hand. Without lytic proteins, the virus cannot replicate, survive in the human population, or exert paracrine effects on neighboring uninfected cells and the tumor microenvironment. Without latent proteins, the virus cannot establish latency and persist for the lifetime of the host. Thus, these two phases of the viral life cycle are interdependent on one another, and the cumulative pathogenesis seen with KSHV infection is a contribution of both lytic and latent genes. Although there is no firm answer to the question of how lytic genes contribute to

KS tumor development, several (nonexclusive) possibilities can be considered:

1. Latent KSHV infection is not clearly immortalizing *in vitro* using current culture conditions, which distinguishes it from EBV. If spindle cells do not proliferate indefinitely, then for a tumor mass to grow, KSHV-positive cells that die must be replaced by newly infected cells. The source of such cells could be generated from *de novo* infection of endothelial cells with virus produced from lytically replicating cells.
2. When recently infected cells bearing latent KSHV genomes undergo sustained proliferation *in vitro*, they lose their viral genome.²⁵⁴ This is supported by the consistent observation that when infected KS spindle cells are explanted from clinical specimens and placed in culture under conditions that favor their proliferation and expansion, they rapidly lose their viral episomes but retain their transformed nature.^{13,178,209} This instability is likely the cause of the relative clinical indolence seen with KS, because cells that divide and proliferate aggressively may lose their viral latent episomes and thus their virally bestowed survival advantage. Thus, lytic replication may be continuously needed for KS development to infect and restore latent infection to spindle cells that have lost their viral genomes. Some experimental evidence indicates that selective pressures exist *in vivo* to retain the KSHV genome, and these are different from those of explanted KSHV-infected cells in culture.^{15,481}
3. Another way that lytic KSHV replication may contribute to KS pathogenesis is through activation of three processes required for KS development: proliferation, inflammation, and angiogenesis. Because fully lytically infected cells die, they are not able to contribute to the proliferative component of the disease. However, in the context of abortive lytic replication, the lytically infected cells can produce paracrine factors that support the inflammatory and angiogenic nature of the lesion. As described earlier, KSHV encodes multiple secreted signaling proteins expressed during the lytic cycle—examples include the three viral CC chemokines and vGPCR. The viral chemokines exhibit chemotactic properties for both Th2 cells^{626,635} and endothelial cells.²⁷⁶ Polarization of local T cells away from Th1 responses might inhibit antitumor cytotoxic responses, whereas the effect of viral chemokines on endothelial chemotaxis suggests that KS lesions are likely to recruit more endothelial cells for latent or lytic infection. Indeed, the application of the viral chemokines to chick chorioallantoic membranes stimulates angiogenesis.^{57,635} Moreover, vGPCR is a potent signaling protein, as discussed previously, and is capable of activating prosurvival, proangiogenic, and proliferative cellular pathways.
4. Finally, it is also possible that some lytic proteins are expressed outside of the traditional lytic cycle—if not during the canonical latent phase, then perhaps in alternative latent phases, which may occur in response to intra- or extracellular signals or microenvironment cues, which allows a specific lytic gene to be expressed in the absence of other lytic genes.

Conversely, one conundrum is the ability of a subset of latent proteins to up-regulate inflammatory cytokines. Several latent proteins are linked to the induction of inflammatory responses, including vFLIP, K15, and kaposin B, as described

earlier. Cytokines play important roles in KS and MCD pathogenesis, and it is likely that these viral proteins induce cytokine production in KS and MCD. Although understandable from a pathogenesis standpoint, from an evolutionary point of view, it appears contradictory that KSHV would embed such proinflammatory biology in the heart of its latency program. In contrast, many viruses encode proteins that prevent inflammatory responses or evade those they cannot ablate.⁴²⁰ This conundrum remains unresolved. It is possible that cytokines are important to maintain latency in naturally infected cells *in vivo*, or for sustaining the viability of such latent cells. Alternatively, an inflammatory microenvironment may help to recruit KSHV-permissive cells to sites of viral infection, thereby facilitating viral spread from cells undergoing lytic reactivation. The fact that some of the latent viral proteins also possess antiapoptotic activity suggests that these viral proteins acting in concert may negate the negative effects of proinflammatory cytokines, whereas the positive effects of these cytokines (e.g., recruitment of target cells) are retained. In addition, there is increasing experimental evidence suggesting that expression of lytic genes (at least vGPCR) in small subsets of cells can augment the proliferation or tumorigenicity of cells expressing latent genes (such as vFLIP and vCyclin).^{472,474}

The identity of the origin of the KSHV-infected tumor cells remains unresolved. One report suggested that bone marrow precursors serve as a reservoir for KSHV.⁵²⁴ Primary mesenchymal stem cells (MSCs) in human bone marrow were shown to be susceptible to KSHV in tissue culture.⁵²⁴ Human CD34+ hematopoietic progenitor cells (HPCs) were also subjected to KSHV infection and differentiated *in vitro*.⁷¹⁶ Infection of CD34+ HPCs with a recombinant GFP-containing KSHV followed by reconstitution with KSHV-infected CD34+ HPCs showed that the virus could be detected in human CD14+ and CD19+ cells recovered from NOD/SCID mouse bone marrow and spleen following infection.⁷¹⁶ These results suggest that KSHV can establish persistence in CD34+ HPCs, and this may serve as a KSHV reservoir to allow the virus to be disseminated to B cells and monocytes after differentiation.⁷¹⁶

EXPERIMENTAL SYSTEMS FOR STUDYING KAPOSI'S SARCOMA-ASSOCIATED HERPESVIRUS

Animal Models

KSHV does not establish persistent infection in mice, hence humanized mouse models have been used. Early studies showed that C.B-17 SCID mice implanted with human fetal thymus and liver grafts (SCID-hu Thy/Liv mice) were susceptible to KSHV infection, with an early phase of lytic replication and subsequent sustained latency.¹⁸⁰ Viral gene expression in CD19+ B lymphocytes was observed, and infection was inhibited by ganciclovir. However, no disease was evident in the infected animals.¹⁸⁰ In another humanized model, NOD/SCID mice with functional human hematopoietic tissue grafts (NOD/SCID-hu mice) were also injected with KSHV. A portion of these animals generated human KSHV-specific antibodies. Antiviral treatment of the NOD/SCID-hu mice with ganciclovir led to prolonged but reversible suppression of KSHV DNA and RNA levels, suggesting that KSHV can

establish latent infection *in vivo*.⁵²³ Human CD34+ cells have been infected *in vitro* and followed in immunodeficient mice, also without any disease.⁷¹⁶ Another reported model of KS was the use of engrafted human skin in SCID mice, into which KSHV was injected. Eighty percent of these mice developed erythematous and angiogenic lesions; however, none developed tumors or locally invasive disease.²¹²

Viruses related to KSHV from other species (e.g., murine herpesvirus 68 [MHV68], RRV, and HVS) are used as experimental models of KSHV pathogenesis (reviewed in 37,160). However, *in vivo*, KSHV infection is restricted to the human population, and no natural infection of any other species has been identified. KSHV is not successfully transmitted in small animal experimental hosts. Implantation of PEL into immunodeficient mice leads to tumor engraftment but not to spread of virus or infection in murine tissues.^{58,533} As described previously, SCID/hu mice transplanted with human lymphoid tissues display infected human B cells within the implant; however, there is no spread to the surrounding mouse tissue, and no disease state developed in these animals.¹⁸⁰

A recent study has shown that KSHV can be successfully transmitted to New World primates, specifically common marmosets (*Callithrix jacchus*).¹²⁰ Infected common marmosets displayed antibody reactivity to KSHV, and LANA protein and KSHV genomic DNA could be detected in PBMCs from these animals, indicating that KSHV could establish persistent infection in these animals.¹²⁰ One KSHV-infected animal developed a KS-like skin lesion consisting of spindle cells and infiltrating leukocytes.¹²⁰

Xenograft models have been very useful for the study of pathogenesis and to test various potential therapies. Xenograft models of PEL have been reported by several laboratories,^{49,58,329,575,610} and PEL cell lines expressing firefly luciferase have allowed *in vivo* tracking of tumor growth (BC-3-NFκB-luc).³²⁹ Xenograft models of KS have also been reported; however, these have used cell lines such as SLK, KS Y-1, and KS-IMM, which were obtained from KS patients but lacked KSHV.^{209,284,557,584} Other cell implantation models include injection of human endothelial cells that have been infected with KSHV *in vitro*¹⁵ and mouse bone marrow cells that have been transduced with a KSHV BAC.⁴⁸¹ These models have provided interesting biological insights and are particularly important because they assess the effect in the context of the entire virus. A related system that has been used to evaluate the interaction of cells expressing a lytic gene (vGPCR) and cells expressing latent genes (vFLIP and vCYC) is the implantation in mice of endothelial cells transduced to express viral genes.⁴⁷² These important studies have confirmed that KSHV can produce vascular tumors, that vGPCR is a critical viral gene for this process, and that there is a selective pressure *in vivo* for viral maintenance.

Cell Culture Models of Infection

To determine parameters of KSHV tropism and transmission, many different cell culture systems have been developed as experimental models to examine these events. The first successful cultivation of cells containing KSHV utilized PEL from AIDS patients with advanced disease.^{110,563} These cells grew as ascites tumors in the KS patients and were readily established in cell culture. A panel of these lines has now been established from both EBV-positive and EBV-negative cases of PEL.^{23,58,92,99,110,219,340} These cell lines have complex, hyperdiploid

karyotypes with multiple structural abnormalities, a few of which are recurrent (trisomy 7, trisomy 12, and aberrations in the proximal long arm of chromosome 1 [1q]).^{186,570,705} However, in general, they do not contain structural alterations in common genes involved in lymphomagenesis (such as cMyc, p52, RAS).⁴⁸⁷ PEL cells predominantly harbor latent KSHV episomes⁵⁶³ with only a handful of latent viral genes being expressed, and virus is not produced. However, in most experimental systems, 1% to 5% of PEL cells display lytic replication with the viral genome being expressed in a temporally regulated fashion, resulting in viral DNA replication and yielding infectious virions as described earlier. The viral titers are quite low but can be greatly increased by the addition of chemical inducers (e.g., phorbol esters) or the HDAC inhibitors (e.g., sodium butyrate and valproic acid).^{467,468,564,602} Chemical inducers reactivate 15% to 30% of latent PEL that begin to exhibit lytic gene expression. Virions isolated from PEL have been utilized for structural studies of the virus particle^{38,40,173,174,495,656,714,738} and for studies of infection studies *in vitro* and animal infectivity studies *in vivo*. These cell lines have also been utilized for serologic assays.

Although cell lines established from patients with advanced KS do exist (SLK, KS Y-1, and KS-IMM), these lack the KSHV genome and are therefore not useful for virological studies. Therefore, immortalized endothelial cell lines have been generated that contain the KSHV genome. Although these in general do not result in stable viral infection, a few cell lines have been generated that do appear to maintain the virus and grow indefinitely. The first such system used dermal microvascular endothelial cells immortalized with human papillomavirus E6 and E7 prior to infection with KSHV.⁴⁷⁹ Another important cell culture system was generated by infecting telomerized endothelial cells (TIVE) to generate long-term cultures (TIVE-LTC).¹⁵ Recently, a new KSHV-infected cell line named KSHV-iSLK and expressing an inducible RTA gene, has been shown to be efficiently induced by doxycycline. These cells seem to produce increased quantities of infectious KSHV virions.⁴⁸³

Most KSHV-infected cells *in vitro* result in viral latency and not lytic replication. These include common cell lines (e.g., HeLa and HEK293).^{39,670} Human cell lines of fibroblastic, endothelial, and epithelial lineages and rodent cell lines (3T3 and BHK) can all support latent infection *in vitro*.^{39,143,213,357,479,577,647,670} Thus, the entry machinery for KSHV is likely distributed across different cell types, and infection in culture is highly amenable and often does not parallel the pattern of infection seen *in vivo*. Established cell lines (e.g., HEK293, TIME, Vero, HFF) that are readily infected can also be induced to reactivate by the same chemical stimuli mentioned earlier for PEL (e.g., TPA or sodium butyrate).

Oral Infection Model

KSHV has been shown to infect epithelial cells, including those from the oral cavity.^{193,311,597,669} Indeed, KSHV has been detected in the saliva of KSHV seropositive individuals^{54,339,355,525} and is also known to be transmitted orally to children from KSHV-positive breast-feeding mothers.^{71,166,432,454} Tissue culture-based infection of oral keratinocyte raft cultures with a recombinant KSHV virus resulted in latent infection in the basal layer; however, when these keratinocytes differentiated, lytic replication was induced and virions were produced at the epithelial surface.³¹¹ Interestingly, early keratinocyte

differentiation did not result in lytic replication in cells attached to a substratum and only occurred in the suprabasal cell layer.⁵⁹⁷ Consistent with this model of adherence-dependent latency, keratinocytes that were differentiated in a suspension activated lytic KSHV.⁵⁹⁷ It appears that the engagement of integrins on the KSHV-infected cell surface plays a key role in maintaining latency and preventing reactivation. *In vivo*, it is likely that virus present in oral epithelial cells is subsequently transmitted to tonsillar B cells where the virus can establish lifelong latency.

Recently, it was shown that KSHV can infect both T and B cells from primary tonsillar explant cultures.^{279,482,484} T cells, however, do not support lytic replication (they display abortive replication); B cells spontaneously produce substantial amounts of infectious virus. When mixed cultures of B cells and activated T cells were exposed to KSHV virus, production was not seen unless the T cells were removed from the cultures or the culture was spiked with immune suppressants. Thus, it appears that oropharyngeal activated T cells recognize ligands on KSHV-infected B cells and suppress lytic replication thereby promoting latency.^{279,482,484} Furthermore, when human tonsillar cells were infected with KSHV and analyzed using multispectral imaging

flow cytometry (MIFC), LANA expression was mostly seen in cells that expressed the lambda light chain of the BCR.²⁷⁹ The KSHV-infected B cells displayed increased expression of Ki67 and IgM and IL-6 receptor. They proliferated and also displayed blast morphology. All of these characteristics are similar to those seen with MCD, which are IgM lambda-expressing plasmablasts.²⁷⁹ Thus, it is likely that oral transmission of KSHV leads to latent infection of a subset of tonsillar IgM lambda-expressing B cells than can expand and resemble plasmablasts.

Taken altogether, these observations suggest several possibilities through which KSHV could establish infection in endothelial cells and B cells *in vivo* (a putative model is shown in Fig. 65.17):

1. It is possible that the virus first infects the oral epithelium from which it is shed into the saliva and can then subsequently infect either endothelial cells or B cells in the oral submucosa.^{193,482,597}
2. It is equally possible that the virus can directly infect B cells (and plausibly endothelial cells) in the oral submucosa through a break in the mucosal epithelium, as described previously for KSHV infection of tonsillar B cells.⁴⁸²

FIGURE 65.17. Hypothetical model of Kaposi's sarcoma-associated herpesvirus (KSHV) infection in the oral cavity. This model is based on various tissue culture studies and correlative measures of viral loads in different compartments *in vivo*. Several possible scenarios are depicted to indicate how KSHV establishes latency in B cells and endothelial cells following primary infection.

- Because KSHV-infected monocytes and macrophages have been detected *in vivo*,^{55,514,612} it is also conceivable that KSHV can directly infect these cells in the oral submucosa or indirectly through oral keratinocytes.
- Although KSHV has not been detected in DCs *in vivo*, it can infect these cells *in vitro*,^{283,556} which raises the possibility that these cells might also be directly or indirectly infected by KSHV in the oral submucosa.

It is important to note that the model described above is hypothetical and is based on different tissue culture studies and correlative measures of viral loads in various compartments *in vivo*. However, it provides some insight into how KSHV can establish latency in B cells and endothelial cells *in vivo*.

EPIDEMIOLOGY

Age

KSHV infection can occur at any age, beginning in early childhood. Reports of children with KS in endemic regions first indicated that viral transmission of KSHV can occur during childhood.⁶¹⁶ Studies evaluating the age in which viral transmission occurs have been possible in subequatorial Africa, where prevalence of KSHV is highest. These studies have largely shown that infection occurs at an early age, arguing for nonsexual transmission. The presence of antibodies to KSHV increases gradually with age,^{62,82,84,235,425,453,455,537} with as many

as 15% of children under 2 years of age having been exposed to KSHV in endemic areas. Closely following puberty, seroprevalence of KSHV continues to rise through early to mid adulthood, which is a pattern suggestive of inefficient heterosexual transmission,^{25,198} with close to half of the population being seropositive by age 50 years⁸³ (Fig. 65.18). There is a strong familial association, with a higher likelihood of a child being positive if the mother or a sibling is positive for the virus. A large study (>2,500 participants) was recently conducted to address whether sociodemographic, behavioral, and biological factors were associated with transmission in rural Uganda. This study confirmed that in this setting, infection is mostly acquired from intrafamilial contacts in childhood and that it continues into adulthood, most likely through nonsexual routes.⁸⁴ As many studies from different areas used variable methodology to assess the seroprevalence, analysis using a single method was conducted to determine the presence of antibodies among a cohort of more than 6,000 people from four sub-Saharan countries in Africa. This study showed that in addition to age, other factors impacted on the seropositivity to KSHV. These included higher rates of infection occurring in rural areas, geographic variation (highest seroprevalence in West Nile, Uganda, of 70% and lowest in Nigeria of 23%), and gender (higher in men than in women).⁵³² This study also nicely confirmed that variations in KSHV seropositivity parallel the cumulative incidence of KS (as shown in Fig. 65.18, which is based on a compilation of multiple studies). Regional variation was also shown in a study evaluating seroprevalence

FIGURE 65.18. Kaposi's sarcoma-associated herpesvirus seroprevalence among children in South Africa (top) and Uganda (bottom) by age. The n values underneath bars refer to the overall number of children in each age group. (From Butler LM, Dorsey G, Hladik W, et al. Kaposi sarcoma-associated herpesvirus (KSHV) seroprevalence in population-based samples of African children: evidence for at least 2 patterns of KSHV transmission. *J Infect Dis* 2009;200:430–438, by permission of Oxford University Press.)

in China, where higher rates were found in the Uyghur, Mongolian, and Kazar ethnic groups, in which most of the cases of KS occur, as compared to the Han people.⁶⁸⁵

Routes of Transmission

KSHV has been found in maternal saliva and in breast milk in endemic areas, arguing for an oral/salivary route of transmission in African children.^{71,166,432,454} Analysis of a cohort of Italian patients with classic KS and their first-degree relatives showed that infection was significantly higher than in healthy controls. These relatives, which included spouses' siblings and offspring, were found to contain viral DNA in their saliva, indicating that close contact contributes to the spread of KSHV and that this spread can occur via nonsexual routes, although sexual transmission in the spouses could not be excluded.⁴³⁴

In contrast to endemic areas (Africa and the Mediterranean Basin), in western Europe and the United States, which are zones of low prevalence (seropositivity 1%–7%), infection is generally acquired sexually; prepubertal children are uninfected, whereas infection rates rise in adulthood, coinciding with sexual activity. Sexual transmission occurs efficiently among men who have sex with men, where seroprevalence can range from 25% to 60%.^{127,228,326,445,608,618} In this group, there is a clear linkage to infection and the number of sexual partners.⁴⁴² Seroprevalence rates tend to be lower among women than men,³²⁴ although rates of infection among female attendees of sexually transmitted disease clinics and commercial sex workers are elevated,^{96,164,304,326} suggesting that heterosexual transmission to females occurs. The finding that virus is consistently detected in saliva,^{525,669} and only sometimes in genital secretions,^{88,177,525,527} favors an important role for salivary virus-mediated sexual transmission.

The possibility of blood-borne transmission through blood transfusion has been witnessed, and there is evidence that it may

occur, albeit rarely. One prospective observational cohort study of transfusion recipients was conducted in Uganda, where the seroprevalence among blood donors was very high, leukocyte reduction was not used, and blood storage time was usually short. In this study, an estimated 12 of the 425 patients who received KSHV-seropositive blood were infected by transfusion. Other studies have confirmed that in some settings, transfusion may lead to acquisition of KSHV, and a couple of case reports have documented transfusion-associated KS.^{3,515,685} In contrast, a study in the United States that evaluated a historical cohort of participants in the Transfusion-Transmitted Viruses Study showed that there was no statistically significant difference in KSHV seroconversion in the transfusion and nontransfusion groups.⁹⁷ The question of whether organ transplants should be screened has also been raised. Although the incidence of KS is highly increased in organ transplant recipients, this is mostly attributable to reactivation as a consequence of immunosuppressive therapy. However, molecular studies have documented that the KSHV originated from the donor in some instances.⁴²⁴ Thus, some investigators have advocated for screening for organ transplantation and for blood transfusion in endemic areas; however, there are no formal guidelines.

Morbidity and Mortality

The major disease caused by KSHV is KS, and the incidence of this disease globally varies widely (Fig. 65.19). However, KS is now one of the most common cancers in many subequatorial African countries, where it is associated with significant morbidity and mortality,⁶¹¹ both of which increase when individuals are co-infected with HIV. KS incidence is 1 in 100,000 in the general population, whereas in HIV-infected individuals, the incidence is around 1 in 20,^{222,699} increasing to almost 1 in 3 in HIV-infected gay men prior to the introduction of highly active antiretroviral treatment (HAART).⁴⁶ KSHV can be detected in

FIGURE 65.19. Cutaneous lesions of Kaposi's sarcoma (KS). Upper left: Leg of human immunodeficiency virus (HIV)-negative patient with patch lesions. Lower left: Multiple nodules in arm of an individual with acquired immunodeficiency syndrome. Right: HIV-infected individual with extensive involvement of lower extremities by KS. (Courtesy of Dr. Susan Krown.)

PBMCs of HIV-infected individuals with KS.⁶⁹⁹ Individuals who acquire KSHV infection with pre-existing HIV infection have a significantly higher risk of developing KS; almost one in two develops KS, indicating that in this setting, KSHV is one of the most oncogenic viruses in humans.⁴⁴⁴ This evidence suggests that an already damaged immune system fosters a higher KSHV load, with subsequent KS development. Geographic areas where KS was endemic before the AIDS epidemic have seen a dramatic increase in the incidence of KS. In countries such as Uganda and Zimbabwe, the incidence of KS has increased about 20-fold, such that it is now the leading cancer in men and the second leading cancer in women. One study estimated close to 60,000 cases in sub-Saharan Africa, with an estimated age-adjusted survival for KS of only 12%.⁵¹⁹ Although the incidence of AIDS-KS in the Western world has declined since the widespread implementation of HAART, it remains increased compared to the pre-AIDS era and now occurs in the presence of high CD4 counts and low HIV viral load.^{350,452} For example, KS rates in the San Francisco area for white men were 0.5 per 100 000 people per year in 1973 (pre-AIDS), more than 30 during 1987–1991 (pre-HAART), and then declined to 2.8 in 1998 (post-HAART).¹⁹⁷

Origin and Spread of Epidemics

KS has been grouped into four major epidemiologic forms²²²: classic KS affecting elderly men of Mediterranean or eastern European Jewish ancestry; endemic KS, existing in parts of central and eastern Africa, described long before the HIV pandemic and often affecting children with disseminated lymphadenopa-

thy^{48,507,616}; iatrogenic KS, developing in immunosuppressed individuals, such as after an organ transplant or for autoimmune disorders⁶⁰⁶; and epidemic or AIDS-KS, a major AIDS-defining malignancy. In the Western world, AIDS-KS predominantly affects HIV-infected gay men. However, in Africa, since the spread of HIV, epidemic KS has become more common in both genders, with a lowering of the male to female ratio.⁶⁷³ The incidence of childhood KS has risen more than 40-fold in the era of AIDS in endemic regions.⁷⁴⁶

Lymphadenopathies linked to KSHV infection, namely PEL and MCD, are much more common in HIV-infected individuals. Although MCD has been reported in Africa, KSHV-associated lymphomas appear to be extraordinarily rare in regions that are endemic for KSHV, even in individuals with HIV infection.²⁰¹ However, it is possible that these cases are currently under-reported.

Prevalence and Seroepidemiology

Strong epidemiologic studies suggest that KSHV infection is absolutely required for the development of KS. Studies that utilized the measurement of antiviral antibodies demonstrated that these antibodies are made during primary infection. However, because primary infection gives way to latent infection in the host, seropositivity is a marker for not only past exposure but also the presence of ongoing viral latent infection.

Like the disease incidence, the prevalence varies globally (Fig. 65.20). Individuals with KS have higher anti-KSHV antibody titers than individuals without KS; thus, the overall seroprevalence may be underestimated. However, despite this

FIGURE 65.20. Geographic prevalence of Kaposi's sarcoma (KS) and seroprevalence of KS-associated herpesvirus. The standardized incidence of KS is depicted for males, and data were obtained from the International Agency for Research on Cancer's Cancer Incidence in Five Continents series.¹⁵⁸ The incidence provided for the United States is an average; however, in states including California, New York, Georgia, and the District of Columbia, it can be as high as 6 per 100,000 among some subpopulations, being particularly high among African Americans. According to the National Cancer Institute's Surveillance Epidemiology and End Results (14 registries), the overall incidence of KS in the United States is as follows: non-Hispanic whites, 0.8; white Hispanics, 1.4; blacks, 2.4. In Italy, incidence also varies by region, ranging from 0.2 to 2.2. Incidences of KS in Africa are from Globocan 2002.⁵²⁰ Seroprevalence rates were compiled from multiple publications; when different values from the same country were reported, an average was taken. Values represent those in the general population, usually blood donors. Cohorts comprising human immunodeficiency virus–infected individuals were excluded in the depiction.

caveat and some regional exceptions, there is a strong concordance between KSHV seroprevalence rates and incidence of KS (see Fig. 65.20). Different tests have been used to determine seroprevalence, and these are variably reliable, with some assays overestimating, and others underestimating, the true prevalence. Therefore, some studies are difficult to interpret. Because KSHV encodes multiple latent and lytic antigenic proteins,¹¹⁷ assays have variably targeted these antigens. The earlier studies utilized immunofluorescence using latently infected PEL cells, or PEL cells treated with TPA to induce lytic replication.^{228,326,380,608} Newer-generation methods rely on enzyme-linked immunosorbent assay (ELISA) using recombinant proteins or peptides, most frequently LANA, which is the major latently expressed antigen, or the lytic antigens K8.1 and ORF65. Usually, testing for both LANA and at least one lytic antigen is encouraged, because infected subjects may have detectable antibodies to one or the other^{51,469} and develop seroreactivity to these antigens at different times.

Nearly all KS patients are seropositive for KSHV with current testing techniques. Prospective studies suggest that KSHV infection predates AIDS-KS development and is a strong predictor of KS risk. Fifty percent of men infected with both HIV and KSHV, who received no effective treatment for either agent, developed KS within 10 years.⁴⁴² The association of KSHV infection with KS is also evident from the fact that KSHV viral genomic DNA and viral antigens are present in all cases of HIV-positive or HIV-negative KS.^{294,476} These data indicate that KSHV is the etiologic agent of KS and that KSHV is the *sine qua non* of KS—patients who do not have KSHV infection will not develop KS. Utilization of ganciclovir as a treatment for AIDS patients at high risk for KS reduces KS incidence and further bolsters this conclusion.⁴⁴⁰

Geographic Distribution and Genetic Diversity

KSHV infection is found at variable rates worldwide, with rates lowest in western Europe and America, and highest in Africa.^{164,441,593,701} In Europe, however, KSHV is more prevalent in the Mediterranean region (e.g., Italy and Spain).^{223,700} KSHV isolates from different regions of the world show differences that help to explain KSHV evolution and its relationship with its human host. As described in Figure 65.3, large blocks of KSHV sequence are highly conserved and do not exhibit much variation from different isolates. However, some genomic regions in the virus display remarkable sequence variability, which makes them useful as markers for strain diversity and to track epidemiologic spread. These include regions surrounding the internal sequence repeats and the coding regions directly adjacent to the left- and right-hand TRs—namely, ORFs K1 and K15, respectively. The biochemical functions of these transmembrane proteins were discussed earlier, and here we discuss their sequence variability in the context of KSHV evolution.

ORF K1 is a transmembrane protein whose N-terminal cysteine-rich ectodomain is highly variable; amino acid differences in K1 between geographically disparate isolates range from 30% to 60% of the total residues in the K1 ectodomain^{751,752} (see Fig. 65.20). Importantly, the cysteine residues, N-linked glycosylation sites, and signaling motifs in the cytoplasmic tail are not changed, which reflects the important nature of these amino acids for K1 function. A vast degree of sequence variation occurs in the hypervariable regions of K1,

named V1 and V2, in which amino acids surge to 60%. It is assumed that host immune pressure drives this variability; however, another hypothesis is that this diversity might have been driven by the need to recognize highly polymorphic cell surface proteins.⁷⁵⁰ K1 sequence variation allows for the separation of KSHV isolates into four major subtypes: A, B, C, and D (Fig. 65.21). (These subgroup identifications are also supported by sequence variations in other genomic loci).^{750,751} It is important to note that the viral strains are stable in a given individual, as different samplings recovered from a single patient taken at various time points often yield identical sequences. The A and C subgroups are viral isolates from KSHV-infected subjects in Europe, the United States, the Middle East, and Asia; subgroup B strains are viral isolates from sub-Saharan Africa; and type D strains are found primarily in Australia, southern Asia, and the Pacific islands. These data indicate that KSHV is an ancient human infectious agent that entered the human population at or around the time that modern humans arose in Africa in the early Pleistocene Age.²⁸⁰ The diversification of the main branches (A/C, B, and D) is thought to occur from isolation and founder effects associated with proposed migrations of humans out of Africa: the first (~100,000 years ago) disseminating subtype B through sub-Saharan Africa, the second (~60,000 years ago) spreading subtype D to southern Asia and onto Australia and the Pacific islands, and the third (~35,000 years ago) carrying subgroups A and C to Europe and northern Asia and onto the Americas.⁷⁵⁰ Alternative interpretations of these findings exist as well but seem less likely.⁴⁵⁸ The clustering of subtypes with ethnic and geographic populations also implies that the virus is primarily transmitted in a familial pattern (e.g., vertically from parent to child and horizontally among siblings), with wider horizontal transmission being less efficient. Of course, in the context of the AIDS epidemic, viral spread occurred by a predominantly sexual route.

There is additional sequence diversity at the right-most end of the viral coding region—the K15 coding sequence. Here, the A and C subgroups (and only rare B isolates) display two allelic variants, termed P (for prototype) and M (for minority). The K15 alleles show large sequence differences that sometimes can extend into the adjacent *ORF75* gene (and sometimes up to 20 kb from the right-hand TRs).^{542,750} A functional *ORF K15* gene is preserved in both P and M alleles. The P and M K15 isolates only share 33% amino acid identity. This extensive sequence divergence is consistent with the notion that the allelic variants were generated from recombination events with an unknown progenitor herpesviral genome during the course of evolution. The fact that both M and P alleles exist among KSHV subgroups A and C suggests that this recombination event likely occurred after the first two waves of emigration from Africa, thus allowing for dissemination of these alleles during subsequent emigration to the Middle East and northern Europe.⁷⁵¹ More recently, additional alleles (N and Q) at the right-hand end of the genome have been identified.⁷⁵⁰

The impact of the different strains in pathogenesis has been analyzed in different defined geographic areas, mostly based on K1 sequencing. One study in Brazil showed a significant predominance of A genotypes in KS lesions from HIV-positive patients, whereas C genotypes were found mostly in the HIV-negative setting.⁵⁵³ In China, subtype A was significantly

FIGURE 65.21. Clades of Kaposi's sarcoma-associated herpesvirus based on open reading frame K1 sequence differences. A and C clades cluster together and are typically found in Europe and the United States. B clade isolates are from sub-Saharan Africa, and D clades are from Australia and the Pacific Islands. The subgroups within each clade are denoted by numbers following the clade letter (e.g., C1-6). Many of the isolates shown here are from commonly used primary effusion lymphoma cell lines, including BC-1, BC-3, and BCP-1. (From Zong JC, Ciufo DM, Alcendor DJ, et al. High-level variability in the ORF-K1 membrane protein gene at the left end of the Kaposi's sarcoma-associated herpesvirus genome defines four major virus subtypes and multiple variants or clades in different human populations. *J Virol* 1999;73(5): 4156–4170, with permission.)

more frequent in mucosal KS lesions than subtype C.⁷³⁴ One study in Italy showed that patients with rapid progression of KS and higher blood viral loads contained type A KSHV, whereas C type was mainly present in slowly progressing patients.⁴³³

Co-Factors

Although KSHV infection is necessary for KS to develop, it is not sufficient and co-factors have been identified. Globally, the presence of antibodies to KSHV is much more common than KS, indicating that on average only about one in ten thousand infected people get the disease (see Fig. 65.20). Clearly, the most important co-factor is HIV infection. It is not yet evident if immunodeficiency itself is the main determinant of KS or whether HIV has a more direct role. Individuals with iatrogenic immunosuppression, particularly renal transplant patients, also have an increased risk for KS, although not as great as that seen with HIV infection. This may reflect differences in KSHV infection rates, rather than HIV-specific causes, or differences in immune dysfunction; however, a direct role for HIV as a co-factor has not been excluded.

Potential contributions from host genetic factors have been reported, including genetic polymorphisms of inflammatory and immune-response genes. Classic KS risk is associated with diplotypes of interleukin-8 receptor β (IL8RB), IL-13,⁷⁶

and certain HLA haplotypes.^{154,185} Transplant KS risk is associated with an IL-6 promoter polymorphism,²³² and genotypes of Fc γ RIIIA may influence the development of KS in HIV-infected men.³⁷⁷ Thus far, these association studies have only shown a relatively small overall increased risk and have not included very large patient cohorts.

Environmental exposures have also been evaluated and found to have an effect on KSHV seroprevalence or incidence of KS. These include regional variations associated with certain volcanic soils, arthropod bites, and living in rural areas.^{532,553,734,745}

These data suggest that common host genetic variants, in addition to co-infections, environmental factors, timing, and possibly routes of infection, all contribute to the oncogenic outcome of KSHV infection.

CLINICAL DISEASE

Kaposi's Sarcoma

Clinical Features

Moritz Kaposi first described five patients with a hemorrhagic sarcoma of the skin and mucous membranes, but also involving internal organs, as appreciated during postmortem

examination.³²⁰ He described an aggressive tumor; however, this form was eventually recognized to be a rare, frequently indolent disease confined to the skin, mostly occurring in older men of Mediterranean and eastern European origin and referred to as sporadic or classic KS. An endemic form of KS was recognized and described by the early 1960s, occurring in sub-Saharan Africa.⁴²⁷ Although African KS was histologically indistinguishable from the sporadic form, it tended to be more aggressive, and a lymphadenopathic form was documented to occur in children.⁶¹⁶ Subsequently, patients receiving immunosuppressive agents, such as solid organ transplant recipients, were also found to develop KS, which has been designated as iatrogenic KS.²⁷⁸ With the advent of AIDS, KS was found to occur with greatly increased frequency, therefore referred to as epidemic KS. In the context of HIV infection, KS was reported to have a much more aggressive clinical behavior, with frequent dissemination to internal organs.²¹⁶

KS can have a variable clinical presentation, ranging from limited to fulminant disease, where generally it tends to be more indolent in sporadic KS and more aggressive in Africans and in individuals with AIDS. However, in all epidemiologic subtypes, there is a range and overlap in clinical presentation (with the exception of pediatric KS that only occurs in Africa, with very rare exceptions). Cutaneous lesions are most common in the lower extremities, face, and genitalia but can appear anywhere¹³⁶ (see Fig. 65.19). In the context of HIV infection, the appearance of cutaneous KS lesions in visible areas may reveal AIDS and carry a heavy psychosocial burden because of existing stigma. Cutaneous KS lesions are typically multifocal and have the appearance of papules, patches, plaques, or nodules, and there can be fungating lesions and tumors. Among these, the patch lesions are considered to be of an early stage, and other forms are considered more advanced. However, whereas these definitions are useful as dermatologic descriptors, in practice these distinctions frequently do not reflect disease progression; several forms can appear simultaneously. There can be patch-type lesions comprising large areas or nodules with limited disease. Lymphedema may be extensive. KS can also involve noncutaneous sites. Particularly common is involvement of the oral cavity, which can be the initial site of presentation. KS can also affect practically all internal organs, most frequently the gastrointestinal tract, lungs, and lymph nodes. In children, lymph node involvement signifies a poor prognosis subset, whereas in adults, focal lymph node involvement is quite common and does not signify the same poor prognosis as other visceral disease.⁴⁸⁵ A clinical classification scheme was proposed for AIDS-related KS by the AIDS Clinical Trials Group (ACTG) Oncology Committee.^{351,352} This staging system incorporates extent of tumor, where T0 (good risk) is when KS is confined to skin and/or lymph nodes and/or minimal oral disease (i.e., non-nodular KS confined to the palate), and T1 (poor risk) is when there is any of the following: tumor-associated edema or ulceration, extensive oral KS, gastrointestinal KS, or KS in other non-nodal viscera. Other criteria in this classification are severity of immunodeficiency (I0 and I1 with a cutoff of <200 CD4 cells per cubic millimeter) and presence of systemic symptoms. This classification was validated prospectively in the pre-HAART era³⁵²; the study found that the combination of poor immune response and tumor stage most accurately predicted survival. However, more recently, a prospective evaluation of the ACTG staging system conducted in the HAART era showed that the

combination of poor tumor stage and systemic illness identified patients with unfavorable prognosis.⁴⁹⁴

Early lesions can be mistaken clinically for purpura, hematomas, hemangiomas, and dermatofibromas, thus a biopsy is necessary, especially when lesions that are not entirely typical of KS occur. It is important to rule out mimics, such as bacillary angiomatosis and angiosarcoma when KS is associated with systemic symptoms. Other diseases that can be confused with KS clinically include lymphangioma, hemangioendothelioma, hemangiopericytoma, and pyogenic granuloma.

Laboratory Diagnosis

Diagnostic confirmation of KS is done through histopathology. At present there are no blood tests for this disease, mostly because viremia is highly variable, and seropositivity does not necessarily indicate a diagnosis of KS. The histologic features of KS are essentially indistinguishable in the four clinical-epidemiologic forms. In skin, it affects the dermis, and similar to the clinical appearance of cutaneous KS, there is a range in the cellularity and microscopic appearance of the lesions. Lesions are characterized by the presence of jagged, thin-walled, and poorly formed dilated vascular spaces with large endothelial cells that may protrude into the lumen (Fig. 65.22). Between these vascular spaces is a spindle cell proliferation that can range from sparse to significant, sometimes forming sheets and extending irregularly in various directions. These spindle cells are considered to be the KS tumor cells. The elongated nuclei vary in size, and some are atypical, thus resembling a fibrosarcoma. However, the presence of narrow irregular, angulated slits containing erythrocytes among the spindle-shaped cells is a distinguishing feature of KS. These can be intertwined with normal vascular channels as well as lymphatic channels, some of which may show considerable cystic dilatation. There is a variable but consistently present inflammatory mononuclear cell infiltrate composed of lymphocytes, plasma cells, and some macrophages. Red blood cells and hemosiderin pigment are frequently seen, often extravasated between the spindle cells. Small granules of intracytoplasmic or extracellular hyalin material may be identified. Granules of hemosiderin can also be seen within the spindle-shaped cells as a result of phagocytosis.^{79,144} Confirmation of a diagnosis of KS is most commonly done by immunohistochemistry in formalin-fixed paraffin embedded tissues using commercially available monoclonal antibodies to the KSHV LANA (ORF73). Because this protein is essential for viral episome maintenance, it is expressed by all KSHV-infected cells, at least in theory. Using immunohistochemistry for LANA, KSHV is detected in a variable proportion of the spindle cells and endothelial cells lining the vascular spaces (see Fig. 65.22). KSHV can also be detected by PCR in KS biopsies.

Clinical Course

The clinical course of disease can be variable. It can be stable, have marked exacerbations, or even regress, especially in post-transplant patients where immunosuppressive therapy can be adjusted and in HIV-infected individuals who begin antiretroviral therapy. The latter is likely owing to the improvement of immune reconstitution against KSHV,⁶¹ and possibly also attributable to decreased circulating HIV-associated proangiogenic and inflammatory cytokines.²²¹ Interestingly, in some patients, KS may progress dramatically, and even be fatal, upon treatment with antiretrovirals owing to an immune reconstitution

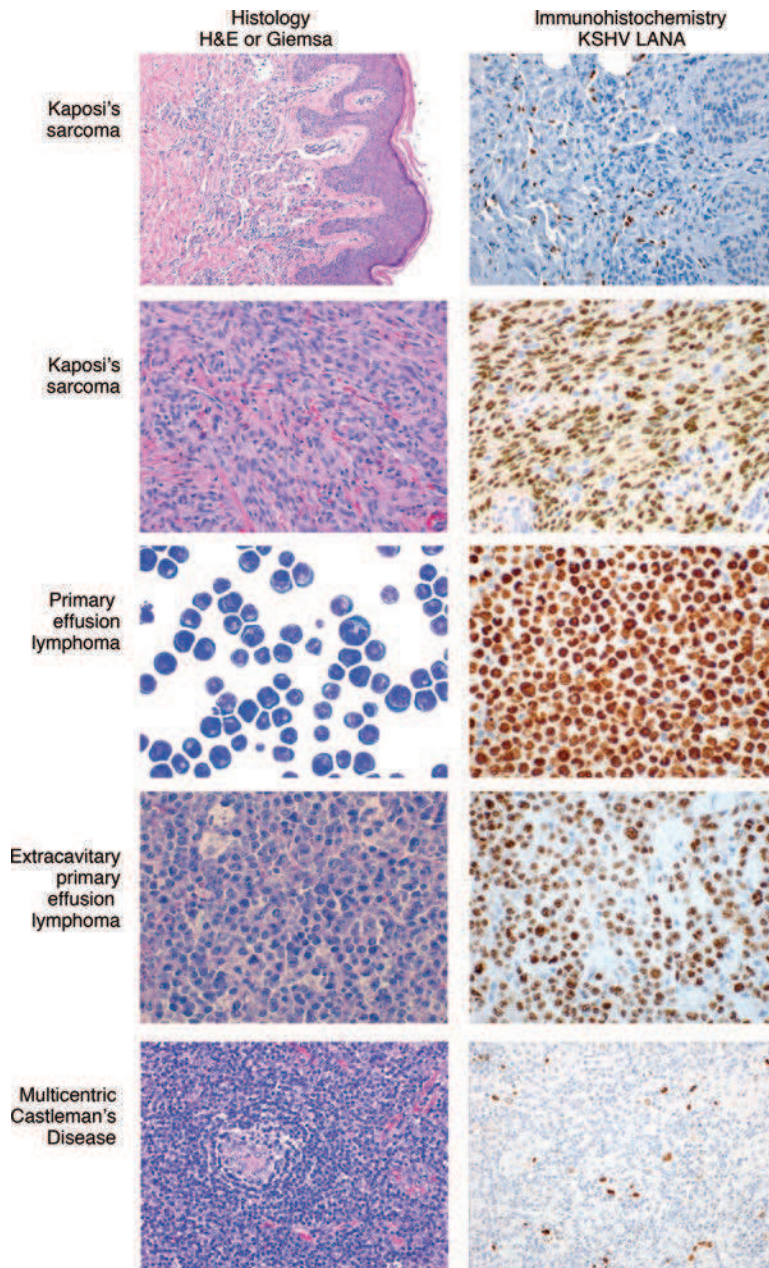

FIGURE 65.22. Histologic features of Kaposi's sarcoma (KS), primary effusion lymphoma (PEL), and multicentric Castleman's disease (MCD). Skin biopsies of two different patients with KS are shown, illustrating the spindle cell proliferation and presence of irregular vascular spaces. **Left columns** are hematoxylin and eosin (H&E) staining of formalin-fixed, paraffin-embedded tissues, and the **right column** shows immunohistochemical (IHC) staining for latency-associated nuclear antigen (LANA), demonstrating broad variability in the number of infected cells. The third row shows a cytospin preparation stained with Giemsa of a PEL on the left, and IHC for LANA on the right, performed on a PEL cell block. The fourth row shows H&E staining of a biopsy from a patient with a non-Hodgkin's lymphoma that was positive for KSHV LANA (**right**), therefore subclassified as extracavitary PEL. The lower row exemplifies a case of MCD, with scattered LANA-positive cells. Original magnification, left column rows 1–2: 20X and 40X, rows 3–4: 60X, row 5: 20X; right column rows 1–2 and 5: 40X, rows 3–4: 60X.

inflammatory syndrome (IRIS).^{64,147,155,379} Onset of IRIS-associated KS flare usually occurs between 3 weeks and 3 months following immunologic and virologic response to antiretrovirals. Early systemic chemotherapy can be effective in suppressing IRIS-associated flares.³⁷⁹

Treatment

HAART has reduced the incidence of AIDS-KS in developed countries and can induce AIDS-KS regression in some individuals. HIV protease inhibitors have been shown to display direct antitumor activity⁴⁷¹; however, non-protease-inhibitors containing antiretroviral combinations also induce KS regression.⁶⁶ However, KS remains a clinical problem with only half of patients achieving complete resolution even with successful antiretroviral therapy.⁴⁹⁹ In addition to HAART, isolated lesions are treated

with radiotherapy and, rarely, surgery. Systemic chemotherapy is useful for the treatment of disseminated disease. Options include doxorubicin, vincristine, bleomycin, and etoposide, as single agents or in combination, as well as paclitaxel and liposomal formulations of doxorubicin or daunorubicin. However, although these treatment modalities can be of great benefit, none is considered curative. Complete regression of cutaneous KS was reported in patients with transplant-associated KS when the immunosuppressive therapy was switched to rapamycin.^{91,627} Good response rates have been confirmed by other investigators in most patients with transplant KS (cutaneous and visceral) when rapamycin was used as the immunosuppressive regimen.^{265,366,748} Data are limited with regard to treatment with rapamycin in patients with KS in other risk groups²⁶⁰; thus, it is too early to know with certainty if the effects are owing to changes in immune response to KSHV

as a result of changing the immunosuppressive therapy or to direct effects on the KSHV-infected lesional cells. These possibilities are not mutually exclusive, and experimental evidence may indicate that both mechanisms contribute to these responses: (a) tumor regression, achieved by switch to rapamycin in two posttransplant KS liver recipients, was shown to correlate with the recovery and the maintenance of both CD8 and CD4 memory responses against KSHV lytic (K8.1) and latent (ORF73) antigens, although one patient who failed to recover CD4 responses to KSHV showed only partial remission³⁴; and (b) KSHV activates the mTOR pathway,^{619,678} and rapamycin is toxic to PEL cells.⁶¹⁰

Primary Effusion Lymphoma

Soon after the discovery of KSHV in KS, viral sequences were also identified in a unique type of lymphoma,¹⁰⁷ referred to as primary effusion lymphoma (PEL) or body cavity based lymphoma (BCBL), which led to the designation of the first cell lines as BC or BCBL. The first reported cases of malignant lymphoma occurring as body cavity effusions were described before the discovery of KSHV as AIDS-associated lymphohematopoietic neoplasms containing EBV and displaying an indeterminate immunophenotype.³³⁸ In this report of three cases, two were lymphomatous effusions, and a B-cell lineage was demonstrated by using DNA-based assays. Subsequent studies recognized that these lymphomatous effusions occurred relatively frequently in HIV-infected individuals.^{247,674} However, they were thought of as unusual AIDS-related lymphomas, and it only became clear that they represent a quite distinct clinicopathologic entity with the recognition of the presence of KSHV within them.⁴⁸⁷ As described earlier, the presence of KSHV in this subset of lymphomas allowed the development of cell lines that have been used as a tool for its propagation, as well as for serologic assays and viral purification. PEL contain many KSHV genomes, ranging from 40 to 80 copies per cell, a feature that has facilitated analysis of this virus.

PEL possess quite distinctive clinicopathologic features. Most importantly, they commonly present as lymphomatous effusions in body cavities, which are usually the pleural, peritoneal, or pericardial cavities, but can also occur in unusual sites, such as an artificial cavity related to the capsule of a breast implant or cerebrospinal fluid.^{470,575} Although they are more common in HIV-positive males, HIV-negative men and women can also develop PEL.^{487,575} Because some KSHV-negative lymphomas, such as Burkitt's lymphoma, can involve body cavities as lymphomatous effusions and KSHV-positive lymphomas can present as solid tissue masses, diagnostic criteria for PEL have been proposed.^{108,487,554} These criteria include immunoblastic-anaplastic large cell morphology (see Fig. 65.22), null cell phenotype (including the lack of B-cell-associated antigen and Ig expression in most cases), and B-cell genotype. The expression of CD138/syndecan-1²²⁰ and hypermutation of the Ig genes⁴⁴⁶ indicated that PEL are at a preterminal stage of B-cell differentiation. This assumption was confirmed by gene expression profiling of PEL,^{307,334,516} as these studies found that PEL resembled plasma cells and had a profile between multiple myeloma and EBV-associated immunoblastic lymphoma.

Lymphomas containing KSHV can also arise with the first presentation as a solid tissue mass with nodal or extranodal involvement, similar to other AIDS-related NHLs. Although some of these patients subsequently develop a lymphomatous effusion, others apparently do not. These cases may be diag-

nosed as diffuse large cell, immunoblastic, or anaplastic large cell lymphomas, in which the presence of KSHV in practically all tumor cells has been demonstrated^{101,113,172,202} (see Fig. 65.22). Most of these are immunoblastic in appearance and have a high mitotic rate and variable amounts of apoptotic debris. Because these lymphomas have some of the defining features of PEL, including a similar morphology, lack expression of B-cell antigens and Ig, and are frequently co-infected with EBV, they have been classified as a variant of PEL, referred to as either extracavitary PEL or solid PEL.

The almost invariable presence of KSHV in PEL suggests that it is necessary for the development of this disease. However, such as in the case of KS, infection by KSHV is necessary but clearly not sufficient, as PEL are very rare tumors, even in populations with high KSHV seroprevalence, accounting for about 3% of AIDS-related lymphomas and 0.4% of all AIDS unrelated diffuse large cell NHLs. Therefore, it is evident that KSHV infection represents only one of several events involved in the development of PEL. Another co-factor appears to be EBV, because many PEL contain both viral genomes. Analysis of the pattern of EBV gene expression in PEL revealed that only EBNA1 was expressed, corresponding to type I latency,^{289,645} and expression of at least one EBV miRNA (BART2) has been shown.^{505,717} PEL lack structural alterations in most cellular-transforming genes frequently involved in lymphomagenesis, with the possible exception of mutations in the regulatory region of BCL-6 (the relevance of which is unclear because PEL do not express BCL-6).^{98,487} The *p53* and *PTEN* genes are rarely mutated.⁵³⁰ Given the limited number of PELs, genome-wide evaluations have limited statistical power. Nevertheless, two fragile site tumor suppressor genes, *FHIT* and *WWOX*, were found deleted in most PEL cell lines.⁵⁷⁰ These observations suggest that KSHV is a critical element for the development of PEL, which is supported by the essential role of several latent viral genes in this disease.

Survival with conventional chemotherapy is very poor, with a median survival of approximately 6 months.^{487,607} Nevertheless, there are case reports of good outcomes with antiviral therapy using bortezomib or rituximab^{60,236,286,400,512,605} or pleurodesis with bleomycin.⁷²⁶

Multicentric Castleman's Disease

Castleman's disease is an atypical lymphoproliferative disorder that encompasses various clinicopathologic entities. There have been pathologic and clinical classifications, which overlap partially. Two distinct histopathologic subtypes were described prior to the identification of KSHV: the more common hyaline vascular type and the plasma cell type.³²⁸ Clinically, Castleman's disease can be localized, or the patient may have multiple enlarged lymph nodes, therefore called *multicentric Castleman's disease*. Approximately 90% of patients with MCD have the plasma cell type morphology. Systemic constitutional symptoms in MCD include fevers, malaise, wasting, hypoalbuminemia, cytopenias, and hyponatremia.⁶⁹² Soon after the discovery of KSHV, an association of this virus with MCD was described.⁶²⁵ There is a strong risk for these patients to develop malignancies, most commonly KS and NHL. Approximately half of MCD cases from immunocompetent individuals have detectable KSHV, whereas in individuals with HIV, almost all patients with MCD have KSHV in involved lymph nodes.

The presence of both KS and MCD in a single lymph node is not uncommon in HIV-positive patients. Notably, MCD, also called *multicentric angiofollicular hyperplasia* in early publications,

is characterized histologically by a vascular proliferation that is reminiscent of KS. Although KSHV has been reported in MCD with both hyaline vascular and plasma cell morphology,³⁶⁴ most cases have closer resemblance to the plasma cell type of MCD. One report indicated that the KSHV-positive cases showed the highest intensity of angiosclerosis and GC and perifollicular vascular proliferation, whereas plasmacytosis was found to be less pronounced than in the KSHV-negative cases of the plasma cell type.⁶³⁷ KSHV-positive cases most likely represent a distinct morphologic variant—resembling more the plasma cell type but additionally showing the presence of larger cells in the mantle zones, which have been called plasmablasts. These contain KSHV and are positive by LANA staining.¹⁹⁰ One study showed that KSHV-positive endothelial cells can also be found in MCD lymph nodes in both HIV-positive and -negative patients.⁷⁵ KSHV-infected B cells can be numerous, coalesce, and form microlymphomas or frank lymphomas. KSHV-infected plasmablasts are B cells that are monotypic but polyclonal, almost invariably expressing IgM lambda.¹⁸⁸ These infected cells are different from PEL cells in terms of B-cell differentiation in that they lack somatic hypermutation of the Ig genes, they express cytoplasmic Ig but lack expression of CD138, and variably express CD27.^{114,188} Therefore, it appears that even if both PEL and MCD originate from KSHV-infected pre-terminally differentiated B cells, infected cells in MCD arise from extrafollicular B cells that did not undergo a GC reaction, whereas PEL may originate from cells that have traversed the GC.

Lymphomas arising in KSHV-associated MCD have been described mainly as occurring in HIV-positive patients¹⁹⁰ and have also been called *plasmablastic lymphomas*. However, there is a type of lymphoma—also referred to as plasmablastic lymphoma and frequently occurring in the oral cavity—that is associated with EBV infection, lacking KSHV. Thus, the formal terminology for the KSHV-associated variant should be “lymphoma arising in KSHV-associated MCD” according to the World Health Organization (WHO) classification.⁵⁵⁴ These lymphomas differ from PEL in several ways. Lymphomas arising in KSHV-associated MCD are EBV negative, do not contain mutations in the Ig genes, and are thought to arise from naive IgM lambda-expressing B cells rather than terminally differentiated B cells. A different rare entity has also been reported, called *germinotropic lymphoproliferative disorder*, in which GC B cells are co-infected with EBV and KSHV.¹⁸⁷

Systemic symptoms in MCD are believed to be a result of production of excess cytokines—in particular, IL-6—and probably both the cellular and viral versions of this cytokine contribute to pathogenesis. vIL-6 has been demonstrated to be expressed in MCD in scattered plasmablasts surrounding the lymphoid follicles.^{93,522,628} Lytic antigens are also expressed more frequently in KSHV-infected cells in MCD than in other disorders associated with this virus, indicating that lytic viral replication may be a feature of MCD.³²² It is possible that MCD falls in the spectrum of KSHV-associated lymphadenopathies, as KSHV-infected cells can be found in lymph node biopsies in patients with HIV-associated lymphadenopathy that lack all the defining pathologic characteristics of MCD.¹¹⁵ Furthermore, an inflammatory syndrome with symptoms very similar to those of MCD has been described in patients with HIV and KS but without a pathologic diagnosis of MCD,⁶⁵⁹ and high serum levels of vIL-6 have been shown in similar patients, suggesting that at least some of the symptomatology of MCD is attributable to this viral cytokine.^{281,511,659}

Median survival of HIV-associated MCD in the pre-HAART era was approximately 14 months.⁵¹³ Various approaches have been used for the treatment of patients with MCD, including cytotoxic chemotherapy, with variable success.⁶³ Evidence of lytic viral expression has led to testing of ganciclovir or other antiviral therapy, with mixed results.^{106,149} The best responses have been obtained with the advent of two different antibody therapies. A humanized antihuman IL-6 receptor monoclonal antibody (tocilizumab) has been reported to result in clinical responses in two studies of patients in Japan; however, the patients did not have AIDS, and only two patients were positive for KSHV.^{503,624} Larger studies have used the humanized monoclonal anti-CD20 antibody rituximab, which has resulted in successful treatment with responses in approximately 70% of patients.^{47,65,149,233} The mechanism of action is not very clear, because KSHV-infected cells in MCD frequently lack expression of CD20.^{114,493} The use of rituximab monotherapy for good performance status patients without organ involvement, and rituximab with chemotherapy for more aggressive disease has been recommended.⁶³ A recent report demonstrated that targeting lytic proteins ORF21 and ORF36 with valganciclovir and zidovudine, respectively, showed very promising results.⁶⁵⁸

PREVENTION AND CONTROL

Prevention of KSHV infection is challenging, especially in endemic areas where the prevalence rate is high. Transmission occurs mainly through saliva within families. Immunization would be ideal; however, to date, no candidate vaccines have been developed. As with EBV, it is difficult to use live attenuated viruses because of the establishment of persistent infection and the potential danger of malignancy development.⁷¹⁵ So far, the clearly successful approach in individuals with HIV has been the use of antiretroviral therapy, which has led to a marked decrease in the incidence of KS, at least in Western countries. This decrease in the incidence of KS is believed to be attributable to improvement in immune function, although a direct role on KS or KSHV has also been proposed.²²⁵ Several reports have shown regression of AIDS-KS following protease inhibitor-based therapy, suggesting that this approach may be better for patients with AIDS and a high risk of KS than the use of nucleoside or nonnucleoside reverse transcriptase inhibitors.^{365,443,708} However, one relatively small prospective study found that both regimens with or without protease inhibitors can decrease KSHV viremia and result in clinical improvement of KS, which occurred more commonly in patients who had undetectable or very low HIV loads.²³⁷ Because a direct effect of HIV infection in KS pathogenesis has been proposed (e.g., owing to paracrine angiogenic effects of Tat), it could be argued that control of HIV infection itself may be partly responsible for the beneficial effects of antiretroviral therapy.^{20,33} Nevertheless, there is evidence that protease inhibitors have a direct role in KSHV. In particular, nelfinavir has been found to inhibit KSHV replication using a recombinant virus assay at concentrations that are achieved in plasma with standard oral dosing.²²⁴ This observation warrants prospective preventive trials of antiretroviral regimens that include nelfinavir in individuals with HIV infection with a high risk of KS, such as those in endemic areas.

Prevention of KS may also be possible in high-risk individuals using inhibitors of lytic replication, such as valganciclovir,

which has been found to reduce KSHV shedding.¹⁰⁵ One study, in which ganciclovir was used for the treatment of CMV retinitis in patients with HIV, showed that the incidence of KS was markedly reduced by 75%.⁴⁴⁰ Although oral valganciclovir did not show beneficial effects on HIV-negative patients with established KS, it appears that compounds that inhibit KSHV lytic replication may have a role in preventing the spread of KSHV and the development of KS.

ACKNOWLEDGEMENTS

We gratefully acknowledge Dr. Don Ganem's assistance in developing and writing this chapter. We thank S. Krown for medical images. We thank D. Dittmer, B. Chandran, S. Krown, A. Bhatt and members of the Damania laboratory for proofreading. We thank J. Jung and R. Renne for helpful discussions, and K. Christensen for scientific illustrations. BD is supported by grants from NCI and NIDCR. EC is supported by grants from NCI. BD is a Burroughs Wellcome Investigator in the Pathogenesis of Infectious Disease and a Leukemia and Lymphoma Society scholar. We sincerely apologize to those investigators whom we could not cite in this chapter due to space limitations.

Adaptive Immune Response to Poxviruses

Antivirals

Expression Vectors

The *Poxviridae* comprise a fascinating family of complex DNA viruses that replicate entirely in the cytoplasm of vertebrate or invertebrate cells. Two members of the family, variola virus (VARV) and molluscum contagiosum virus (MOCV), are obligate human pathogens, and others, such as monkeypox virus (MPXV), can be transmitted from animal hosts to humans and cause severe disease. VARV was the cause of smallpox, a once common and highly lethal disease that altered human history. Smallpox was eradicated in 1977 through a dedicated effort spearheaded by the World Health Organization, nearly two centuries after the introduction of highly effective prophylactic inoculations with cowpox virus (CPXV) and vaccinia virus (VACV). In addition to obvious public health value, vaccination contributed to present concepts of infectious disease and immunity. From a historical perspective, VACV was the first animal virus seen microscopically, grown in tissue culture, accurately titered, physically purified, and chemically analyzed. Moreover, a once prevalent view of virus particles as packets of nucleic acid was revised following the discovery of RNA synthetic activity in purified poxvirus (POXV) virions. This finding sparked investigations that led to the discovery of transcriptase and reverse transcriptase activities in RNA viruses and to the elucidation of structural features of viral and eukaryotic messenger RNA (mRNA), including the 5' cap and 3' poly(A) tail. Recombinant DNA technology

eliminated obstacles to working with such large viruses, and considerable progress has been made in elucidating the cycle of virus replication. Discoveries of virus-encoded proteins that affect cell growth and modulate immune defense mechanisms continue to provide new insights into virus–host relationships. In addition, the development of POXVs as live recombinant expression vectors provides a powerful tool for immunologists and biochemists as well as an alternative approach to the development of vaccines against a variety of infectious agents and cancer.

CLASSIFICATION

Distinguishing properties of the family *Poxviridae* include a cytoplasmic site of replication and a large complex enveloped virion, which contains enzymes that synthesize and modify mRNA and a genome composed of a single linear double-stranded DNA molecule of 130 to 300 kilobase pairs (kbp)

with a hairpin loop at each end. POXVs are divided into the subfamilies *Chordopoxvirinae* and *Entomopoxvirinae*, based on vertebrate and insect host range (Table 66.1). DNA sequencing and bioinformatic analysis confirm the genetic relationship between the POXV subfamilies and further suggest that POXVs are distantly related to *Asfarviridae*, *Ascoviridae*, *Iridoviridae*, *Phycodnaviridae*, *Mimiviridae*, and *Marseillevirus*.³⁹⁸

The subfamily *Chordopoxvirinae* consists of nine genera—*Avipoxvirus* (10 species), *Capripoxvirus* (3 species), *Cervidopoxvirus* (1 species), *Leporipoxvirus* (4 species), *Molluscipoxvirus* (1 species), *Orthopoxvirus* (9 species), *Parapoxvirus* (4 species), *Suipoxvirus* (1 species), and *Yatapoxvirus* (2 species)—and 2 unassigned species (Table 66.1). Members of the same genus are genetically and antigenically related and have a similar morphology and host range. The orthopoxviruses (OPXVs) have been studied most intensively. The species names frequently refer to the host from which it was first isolated rather than the important reservoir species (e.g., rodents are reservoirs for

^aFour-letter abbreviations of species used in text appear in parentheses.

^bPrototypal member.

CPXV and MPXV). VACV, the prototype OPXV, has been propagated as the smallpox vaccine for 200 years and apparently no longer exists in its original host,⁶¹ although vaccine-derived strains are currently circulating in cattle in Brazil and occasionally infect humans.⁷⁰³ DNA sequencing reveals that genes common to camelpox virus (CMLV), CPXV, ectromelia virus (ECTV), MPXV, taterapox (TATV), VACV, and VARV are greater than 90% identical, whereas OPXVs indigenous to the Americas (e.g., raccoonpox, skunkpox, and volepox virus) exhibit greater genetic divergence.²³⁴ CPXV contains all genes present in other OPXVs, suggesting that it resembles the ancestral member of this genus, whereas the other species have lost some genes. Recent analyses suggest that more than one species of OPXV have been grouped under the CPXV species.¹²⁷ The entomopoxviruses are divided into three genera—*Alphaentomopoxvirus* (7 species), *Betaentomopoxvirus* (13 species), and *Gammaentomopoxvirus* (6 species)—and 2 unassigned species based on the insect host of isolation (Table 66.1).

VIRION STRUCTURE

Morphology

The virions of POXVs are large compared to most other well-studied animal viruses and are just discernible by light microscopy. Nevertheless, higher magnification provided by electron microscopy is needed to resolve ultrastructure. The basic infectious form of POXV is the mature virion (MV). As will be

discussed later, an extracellular enveloped (EV) form of VACV consists essentially of an MV enclosed by an additional membrane. Cryo-preparation, which avoids drying artifacts, has been combined with electron tomography to provide a 3-D reconstruction of VACV MVs (Fig. 66.1)¹⁶⁶ that is consistent with classical descriptions derived from thin sections of fixed and dehydrated samples (Fig. 66.2).¹⁷⁸ Reconstructed images of virions have a barrel shape with dimensions of $\sim 360 \times 270 \times 250$ nm. The thickness (5 to 6 nm) and density of the outer layer are consistent with one lipid membrane bilayer, the outside of which appears corrugated because of irregular protrusions extending 3 to 5 nm. The internal structure of the virion is complex, consisting of a dumbbell-shaped core and lateral bodies between the concavities and the outer membrane. The core wall seems to be composed of two layers with an overall thickness of 18 to 19 nm. The inner layer appears continuous, except for a small number of channels, and has a diameter and density consistent with a lipid membrane. The outer layer has a palisade structure made of T-shaped spikes (8 nm in length and 5 nm wide) that are anchored in the putative lower membrane. Freeze fracture and deep-etch electron microscopy confirmed the outer structure of the virion as consisting of a single membrane bilayer with surface corrugations and the palisade structure of the core wall but did not reveal an internal core membrane and questioned its existence.³¹¹ The ultrastructure of the core is not resolved by cryoelectron tomography but appears to consist of two phases: the denser layer just under the core wall has a fiber-like morphology suggesting nucleoprotein. Cylindrical elements that may take an S-shape or more complex flower-like structures, presumably representing nucleoprotein, were visualized by other means within POXV cores.^{349,582} Proteins have not yet been localized to structural features of virions.

Chemical Composition

The mass of a VACV MV is 9.5 fg.²⁹⁴ The principal components of the MV are protein, lipid, and DNA, accounting for 90%,

FIGURE 66.1. Reconstructions of vaccinia virus (VACV) mature virion (MV). **A, B:** Volumetric representations highlighting the outer shape and size of the virions in two orthogonal views along perpendicular axes. **C, D:** Translucent representations showing the complex internal structure of the core. In one orientation (**C**), the dumbbell shape of the core is seen. (From Cyrklaff M, Risco C, Fernandez JJ, et al. Cryo-electron tomography of vaccinia virus. *Proc Natl Acad Sci U S A* 2005;102:2772–2777. Copyright 2005 National Academy of Sciences, U.S.A.)

(From Pogo BGT, Dales S. Two deoxyribonuclease activities within purified vaccinia virus. *Proc Natl Acad Sci U S A* 1969;63:820–827.)

5%, and 3.2%, respectively, of the dry weight.⁸⁷⁴ In contrast, about one-third of fowlpox virus (FWPV) virions is lipid.⁴⁴¹ The lipid components of VACV MVs are predominantly cholesterol and phospholipids,^{150,718,735} whereas FWPV virions also contain squalene and cholesterol esters.⁴⁴¹ Carbohydrate is present in the VACV EV as a constituent of glycoproteins. Spermine and spermidine⁴¹⁶ and trace amounts of RNA⁶³⁰ also have been found in VACV MVs, but their significance is uncertain.

Genome

POXVs have linear double-stranded DNA genomes that vary from 140 kbp in parapoxviruses to 300 kbp in some avipoxviruses. POXVs have inverted terminal repetitions (ITRs), which consist of identical but oppositely oriented sequences at the two ends of the genome.²⁶⁶ The ITRs include an A+T-rich, incompletely base-paired, hairpin loop that connects the two DNA strands⁵³; a highly conserved region of less than 100 bp that contains sequences required for the resolution of replicating concatemeric forms of DNA^{203,482}; variable length sets of short, tandemly repeated sequences⁸⁴³; and up to several open reading frames (ORFs). The ends of the VACV genome are depicted in Figure 66.3. The ITRs are variable in length due to deletions, repetitions, and transpositions.

Complete genome sequences have been reported for at least one member of each *Chordopoxvirus* genus and two *Entomopoxvirus* genera. Nearly 100 genes are conserved in all chordopoxviruses and about half of these can be recognized in entomopoxviruses.⁷⁸⁷ Based on this, several generalizations can be made: **genes are largely nonoverlapping**, tend to occur

in blocks pointing toward the nearer end of the genome, are usually located in the central region if highly conserved and concerned with essential replication functions, and are usually located in the end regions if variable and concerned with host interactions. An ORF map of the VACV genome is shown in Figure 66.4. The arrangement of the central genes is remarkably similar in all chordopoxviruses. A convention for naming VACV ORFs, originating prior to sequencing the entire genome and used for the complete sequence of the Copenhagen strain of VACV, consists of using the HindIII restriction endonuclease DNA fragment letter, followed by the ORF number (from left to right except for HindIII C) within the fragment, and L or R, depending on the direction of transcription. Polypeptide names correspond to gene names, except that L or R is dropped. In contrast, ORFs have been numbered successively from one end of the genome to the other in most subsequent complete POXV genome sequences; nevertheless, the old letter designations have been retained as common names for homologs to provide continuity in the literature. The ORF number of the Western Reserve (WR) strain of VACV, which has been used for the majority of biochemical and genetic studies, is included in tables.

Polypeptide Components

Consistent with their size and complex structure, POXV virions contain a multitude of polypeptides.¹⁵⁶ Approximately 80 virus-encoded polypeptides have been identified by mass spectrometry,^{147,613,870} and 30 have been localized near the exterior of purified MVs by surface-specific labeling, sensitivity to

proteases, extraction with nonionic detergents, or reactivity with virus neutralizing antibodies. The surface proteins can be divided structurally into those with transmembrane domains and those without and functionally into those required for attachment, entry, disulfide bond formation, morphogenesis, and virulence (Table 66.2). **None of the MV membrane proteins are glycosylated, which could have implications for the derivation of the viral membrane.**

Virus cores can be produced *in vitro* by treatment of MVs with a nonionic detergent and reducing agent.²³¹ Nearly 50 polypeptides, distinct from those in the membrane fraction, have been identified in such cores. Of these, about 30 are enzymes, of which at least half are directly involved in early mRNA biosynthesis (Table 66.3); the nonenzymatic proteins may be primarily involved in morphogenesis and structure

(Table 66.4). The F17R, L4R, A3L, and A10L ORFs encode particularly abundant core proteins.

Evidence for a distinct extracellular form of VACV came from vaccine-related studies. Antibodies to inactivated MVs did not protect rodents against an OPXV infection as well as antibodies to live virus or inactivated EVs.⁹² Furthermore, there were differences in the relative neutralizing abilities of the different types of sera. Subsequent studies showed that the EV has an additional membrane and consequently a lower buoyant density.⁶²² The additional membrane contains several unique glycosylated proteins (A33, A34, A56, B5, K2) and one non-glycosylated (F13) (Table 66.5). Of the six EV membrane proteins, only A34 and F13 are conserved in all chordopoxviruses. Although EVs are usually considered as MVs with an additional membrane, that is not precisely true. There is evidence

that MVs contain at least two surface proteins, A26 and A25, that are absent from EVs.⁷⁸³

CELL ENTRY

General Considerations

Investigations into mechanisms used by POXVs to enter cells have been complicated by the existence of two infectious forms: MVs, which have a single outer membrane, and EVs, which have an additional membrane with a different protein composition.⁵⁰⁷ Although the MV is the more abundant form, the EV

is specialized for cell-to-cell spread as will be discussed later. Following cell attachment, however, the EV-specific membrane is discarded and the underlying MV membrane fuses with the cell.⁴¹⁹ The next two sections summarize current understanding of MV and EV entry.

MV Entry

Enveloped viruses typically enter cells by fusion with the plasma membrane or following endocytosis. VACV is versatile in that MVs use both entry mechanisms (Fig. 66.5A, B), perhaps accounting for their ability to enter most cells.^{28,176} Endosomal acidification promotes entry of the virus core into

FIGURE 66.5. Vaccinia virus (VACV) mature virion (MV) fusing with the plasma (A) or endosomal (B) membrane. VACV MVs were deposited on the cell surface by **spinoculation** and incubated at 37°C for 30 minutes. The unpermeabilized cell was incubated with antibody to the D8 membrane protein and labeled with protein A conjugated to gold spheres. The gold particles demonstrate that the viral membrane has fused with the plasma membrane in panel A; the core is within the cytoplasm. (Courtesy of A. Weisberg.)

the cytoplasm following **actin-dependent macropinocytosis** or fluid phase uptake of the large virus particles.^{339,478,504,768,769} There is considerable VACV strain variation regarding the preference for the alternative entry pathways,⁷⁰ which may depend in part on the A25 and A26 proteins.^{133b} Initial studies indicate that myxoma virus also enters cells through a low pH endocytic pathway.⁸⁰¹ VACV enters primary cultures of well-differentiated human airway epithelial cells through the basolateral surface and exits through the apical surface.⁸⁰⁰

Many enveloped viruses contain one or two proteins that mediate attachment as well as fusion with cell membranes. **VACV is exceptional in encoding at least 4 proteins for attachment and 12 dedicated to entry** (Table 66.2). **Cell surface glycosaminoglycans and laminin can mediate MV attachment.**

The protein D8 binds chondroitin sulfate,³³² A27 and H3 bind heparan sulfate^{148,331,426,798} and A26 binds laminin.¹⁴¹ Of these attachment proteins, only D8 and H3 have transmembrane domains. A26 and A27 interact with each other and the A17 transmembrane protein anchors the latter.^{325,626} Individually, the attachment proteins are not essential and heparin appears to have a greater competitive inhibitory effect on strains that preferentially enter by a neutral pH mechanism.⁷⁰

Fusion of VACV with cell membranes was demonstrated many years ago,²²³ but the participating viral proteins were identified only recently. The number of viral proteins required for entry is unprecedented. The 12 proteins implicated thus far are listed in Table 66.2. Most or all of the proteins are components of the entry fusion complex (EFC) or associated with it.⁶⁷⁸ The proteins are each dedicated to entry, because the assembly of normal-looking virions that are unable to initiate an infection occurs despite their repression. Their conservation in all POXVs strongly suggests a common entry mechanism. Three of the proteins, A16, G9, and J5, are related in sequence and were apparently derived from a common gene early in POXV evolution. The entry proteins vary in size from 4 to 43 kD, are nonglycosylated, and do not resemble either type 1 or type 2 fusion proteins of other viruses. Except for G3, I2, and O3, the entry proteins contain conserved intramolecular disulfide bonds that are formed by the cytoplasmic redox system, which is also encoded by all POXVs and will be described later. The EFC proteins are not required for attachment of virions to cells, but most are needed for the initial fusion of viral and cellular membranes.⁴¹⁴ The L1 protein has been reported to bind to cell surfaces and block virus entry.²⁵⁵ Nevertheless, the mechanism of fusion and the function of individual proteins remain to be determined. The anatomy of the complex has not yet been solved, although some interacting partners have been identified.^{535,806,844} The VACV A17 and A27 proteins have also been implicated in membrane fusion,³⁹⁴ but there is no genetic evidence that their activities are required for entry.

EV Entry

Efficient cell-to-cell spread of VACV is mediated largely by EVs that adhere to the cell surface at the ends of long, mobile, finger-like projections that are formed by actin polymerization, as illustrated in Figure 66.6.^{84,737} Deletion of the *A33R*, *A34R*, or *A36R* gene (Table 66.5) prevents actin tail formation and reduces the efficiency of virus spread.^{640,846} However, mutations of the A33, A34, or A36 proteins, which cause enhanced release of EV, can overcome a deficiency in actin tail formation resulting in rapid spread.^{84,383}

For technical reasons, most entry studies have been carried out with free EVs rather than the biologically important cell-associated form. However, the EV membrane is fragile and it is difficult to be sure that the membrane is intact in the majority of particles. Available information suggests that free EVs are taken up by endocytosis much like MVs.⁶⁶⁰ **The entry proteins described earlier are required for cell-to-cell spread of EVs and for low pH-induced syncytia formation, supporting the idea that only the MV membrane is fusogenic.** Consequently, removal of the external EV membrane with exposure of the MV membrane precedes the fusion step because the entry/fusion proteins are located in the latter. Disruption of the outer EV membrane within endosomes was suggested by sensitivity to lysosomotropic agents³⁵²; in addition, electron micrographs

FIGURE 66.6. Scanning electron microscopy of a cell infected with vaccinia virus (VACV). Cells were infected with VACV for 20 hours and then fixed and coated with palladium gold. The arrow points to an extracellular enveloped virion (EV) at the tip of a virus-induced actin-containing microvillus. (Courtesy of A. Weisberg.)

of MVs fusing with the plasma membrane beneath a disrupted EV wrapper have been obtained.⁴¹⁹ Disruption of the EV wrapper at the plasma membrane is dependent on polyanionic molecules or low pH and requires the membrane glycoproteins A34 and B5, which may explain the low infectivity of EVs lacking the A34 protein.^{419,621} The fusion of infected cells to each other, mediated by short exposure to low pH, may mimic the endocytic path by disrupting the outer membrane of virus particles on the cell surface.^{223,277} Mutations of the A56 hemagglutinin or the K2 glycoprotein results in fusion of adjacent infected cells without the need for a low pH trigger.^{671,778}

Superinfection Inhibition

The spread of EVs to uninfected cells may be enhanced by a repulsion mechanism that prevents superinfection of cells that express the A33 and A36 proteins on the plasma membrane and generates new actin protrusions.²¹⁸ Another mechanism operates to prevent fusion of MVs with infected cells: the A56-K2 heterodimer interacts with the A16 and G9 subunits of the EFC.^{780,805,806} There are likely additional processes that inhibit superinfection.¹⁴⁴

Cell Entry and Signaling Receptors

Interaction of the MV with the cell surface triggers a signaling cascade that results in membrane rearrangements and the formation of actin and ezrin-containing protrusions that seem to envelope the virus and are important for virus entry and replication.^{21,189,437,460,478} Further studies suggest that signaling and actin rearrangements are needed for the initial step of fusion of viral and cellular membranes.⁴¹⁴ The lipid composition of the cell membrane is important for entry as depletion of cholesterol inhibits virus penetration.¹⁴⁹ However, specific protein receptors that are required for the penetration step have not yet been identified and could vary with cell type. Proposals

that the epidermal growth factor receptor⁴⁵¹ and chemokine receptors⁴¹² serve as portals of entry for POXVs have not been confirmed.^{344,460} Infectivity of VACV can be increased with phosphatidylserine,³⁵⁴ and an apoptotic mimicry model with a role for a specific phosphatidylserine receptor has been suggested based on reconstitution of delipidated virus.⁴⁷⁸ However, the stereoisomer of phosphatidylserine and other phospholipids not known to signal apoptotic uptake can also reconstitute infectivity, indicating that the putative receptor has broad specificity or that the phospholipids have a different role in enhancement of infectivity.⁴¹³

GENE EXPRESSION

Programmed Expression of POXV Genes

Studies primarily with VACV have led to an understanding of the gene expression program, which occurs exclusively in the cytoplasm: (a) a complete early transcription system is present within the core of virus particles, providing a mechanism for the synthesis of viral early mRNAs soon after infection; (b) the early mRNAs encode enzymes and factors needed for synthesis of viral DNA and for transcription of the intermediate class of genes; (c) the intermediate gene transcripts encode enzymes and factors for late gene expression; and (d) the products of the late genes include the early transcription factors, which are packaged with RNA polymerase and other enzymes in progeny virions (Fig. 66.7). Most studies refer to posttranscriptional gene products as late without distinguishing between intermediate and late classes. However, progress in resolving the intermediate and late gene classes has been made recently,⁸⁶⁷ allowing the construction of the transcription map in Figure 66.4. POXV transcription has been reviewed recently.¹⁰⁴

Regulation of Early-Stage Transcription

Infectious POXV particles contain a transcription system that synthesizes mRNAs that are capped, methylated, and polyadenylated.^{375,376,525,822} A large number of virus-encoded enzymes and factors that are directly involved in the synthesis and modification of mRNA including the multisubunit DNA-dependent RNA polymerase, RNA polymerase-associated protein of 94 kD (RAP94), early transcription factor (VETF), capping and methylating enzymes, poly(A) polymerase, nucleotide phosphohydrolase I (NPH I), and topoisomerase are packaged in the virus particle (Table 66.3). Additional enzymes may have roles in virus assembly, protein processing, or DNA packaging as discussed later.

Following entry into the cytoplasm, virus cores are transported on microtubules to sites of transcription^{128,446} and mRNA synthesis is detected within 20 minutes (Fig. 66.8).⁴¹ RNA/DNA hybridization studies revealed that about half of the vaccinia virus genome is transcribed prior to DNA replication,^{88,556} and genome tiling and deep RNA sequencing have corroborated this.^{30,864,865} Although early transcripts can be divided into two groups based on kinetic cluster analysis, the significance of this is unclear as both are expressed in the presence of protein synthesis inhibitors and therefore can be classified as immediate-early.⁸⁶⁵ The genomic arrangement of early genes is shown in Figure 66.4. The cessation of early gene expression coincides with disruption of the virus core, a process known as uncoating. Electron microscopic images suggest that the nucleoprotein complex

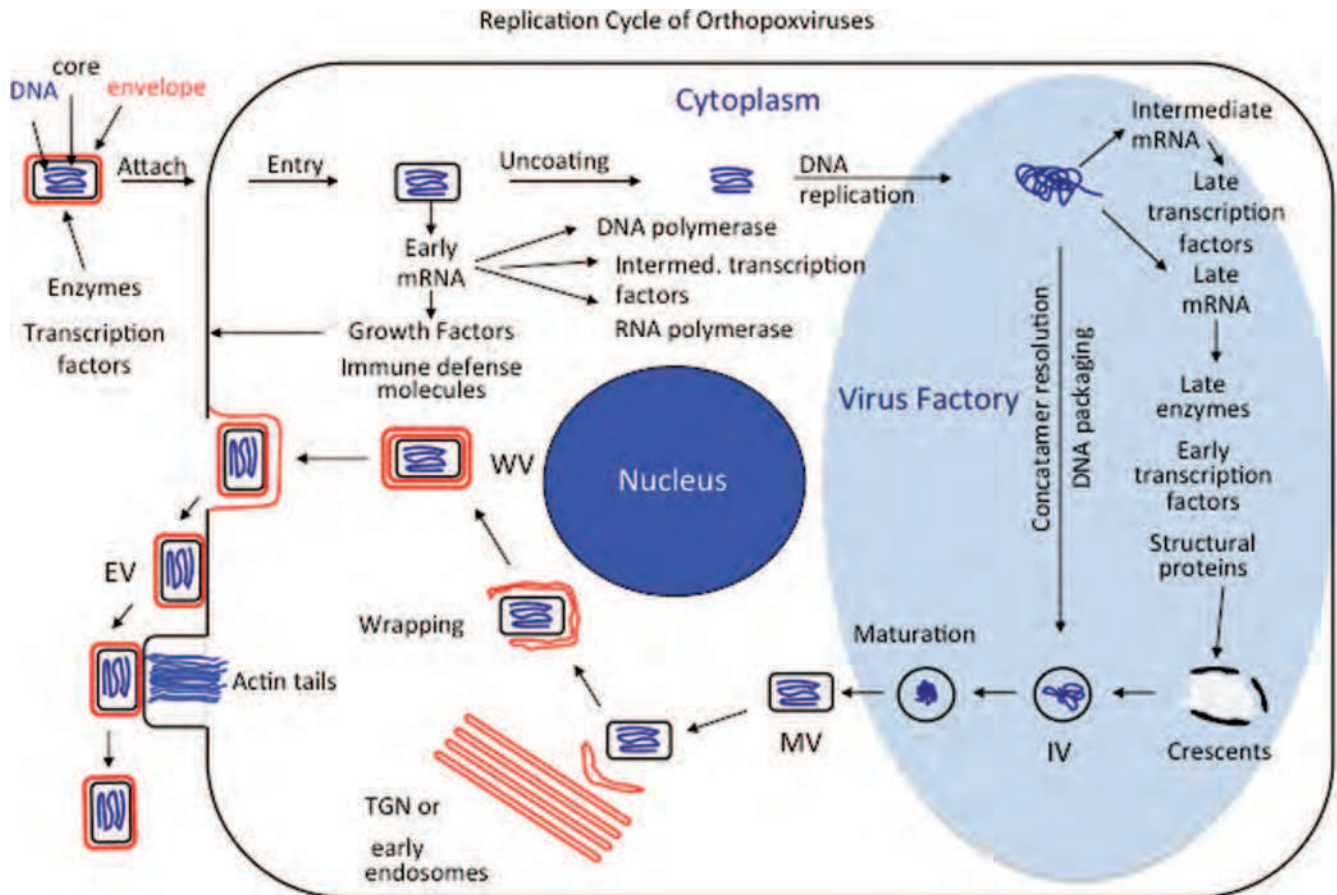

FIGURE 66.7. The replication cycle of vaccinia virus (VACV). Virions, containing a double-stranded DNA genome, enzymes, and transcription factors, attach to cells and fuse with the cell membrane, releasing cores into the cytoplasm. The cores synthesize early messenger RNAs (mRNAs) that are translated into a variety of proteins, including growth factors, immune defense molecules, enzymes, and factors for DNA replication and intermediate transcription. Uncoating occurs and the DNA is replicated to form concatemeric molecules. Intermediate genes in the progeny DNA are transcribed and the mRNAs are translated to form late transcription factors. The late genes are transcribed and the mRNAs are translated to form virion structural proteins, enzymes, and early transcription factors. Assembly begins with the formation of discrete membrane structures. The concatemeric DNA intermediates are resolved into unit genomes and packaged in immature virions. Maturation proceeds to the formation of infectious intracellular mature virions (MVs). The virions are wrapped by modified *trans*-Golgi and endosomal cisternae, and the wrapped virions (WVs) are transported to the periphery of the cell via microtubules. Fusion of the wrapped virions with the plasma membrane results in release of extracellular enveloped virions (EVs).

passes out through breaches in the core wall.¹⁷⁵ If uncoating is prevented by protein synthesis inhibitors,³⁶⁹ early mRNA synthesis is increased and prolonged,^{41,850} suggesting that under normal conditions core disassembly leads to the disruption or disorder of the early transcription apparatus. A putative uncoating protein has been purified but not genetically identified.⁵⁷³

The rapid decline of steady-state early mRNA levels (Fig. 66.8) is due to an enhanced rate of mRNA degradation as well as to cessation of transcription.^{546,668} Degradation of mRNAs is enhanced by the products of the D9R and D10R ORFs,^{564,695} which are decapping enzymes.^{562,565} Presumably, the decapped mRNAs are rapidly destroyed by cellular 5' exonuclease activity. Rapid mRNA turnover may be a mechanism for eliminating cellular mRNA and also viral mRNA at the end of early and intermediate stages.

Early-Stage Promoters and Termination Signals

Transcription of early genes is determined by an A/T-rich sequence upstream of the RNA start site. Saturation mutagenesis of a VACV early promoter defined a critical core region, from -13 to -25, in which many single-base substitutions have a drastic effect on expression.¹⁸⁴ The consensus core sequence derived from an analysis of the region upstream of all annotated early start sites⁸⁶⁴ is consistent with the mutagenesis studies (Fig. 66.9). Transcription initiation usually occurs with a purine, predominantly 12 to 17 nucleotides downstream of the core region. The core motif, however, is present at numerous locations in the genome and appears to be required but not sufficient for transcription initiation. Further analysis correlated a high AT content in the spacer region between the

FIGURE 66.8. Steady-state levels of representative early-, intermediate-, and late-stage messenger RNAs (mRNAs) in vaccinia virus (VACV)-infected cells. Total RNA was isolated from infected HeLa cells at various times after infection and hybridized to antisense RNA probes specific for the 5' ends of mRNAs encoded by the C11R (early), G8R (intermediate), or F17R (late) open reading frames (ORFs).⁴¹ After ribonuclease digestion, the protected probe fragments were analyzed by polyacrylamide gel electrophoresis and the radioactivity quantified. The numbers were normalized to the peak value in each case.

core motif and the RNA start site with active transcription.⁸⁶⁴ Nevertheless, there appear to be many more transcription start sites than annotated ORFs, possibly allowing for the generation of new proteins during evolution. Promoter motifs are conserved between POXV genera, explaining an old phenomenon called nongenetic reactivation, which consists of rescue of a heat-inactivated POXV by co-infection with a second poxvirus belonging to a different genus.^{251,301} Thus, the heat-killed POXV provides the template and the second POXV provides the enzymes for transcription.

The 3' ends of VACV early mRNAs frequently occur 20 to 50 bp downstream of the sequence TTTTNT (abbreviated as T5NT).⁸⁷³ However, termination is actually mediated by U5NU in RNA.⁷⁰¹ T5NT sequences are present near the ends of most but not all viral early genes. When absent, the mRNA tail may extend through the next early gene downstream. *In vivo* studies suggested that the efficiency of termination following a single T5NT is about 80%,²²⁸ although in some cases it is less probably because of RNA secondary structure.^{421,439} T5NT sequences have been noted near the ends of putative early genes of other POXV genera,^{3,122,674} suggesting a similar role in termination. Nevertheless, a VACV genome-wide analysis of the 3' ends of early mRNAs revealed that only about two-thirds had a T5NT sequence within 100 nucleotides upstream, suggesting an additional termination mechanism.⁸⁶⁴ A pyrimidine-rich sequence in the coding strand up to position -25 relative to the polyadenylation site was found regardless of the presence of T5NT, suggesting that it might facilitate termination.

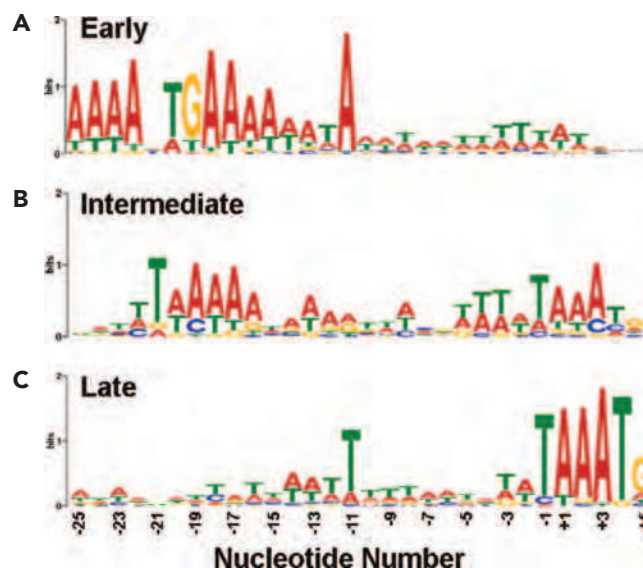

FIGURE 66.9. Motif logos of vaccinia virus (VACV) promoters. Motifs represent early genes (A), intermediate genes (B), and late genes (C); +1 represents the RNA start site. (From Yang Z, Reynolds SE, Martens CA, et al. Expression profiling of the intermediate and late stages of poxvirus replication. *J Virol* 2011;85:9899–9908.)

Enzymes and Factors for Early-Stage Transcription

Soluble extracts of VACV virions can transcribe an early promoter template *in vitro* to generate properly initiated and terminated mRNAs⁶³¹ and therefore provide a source of materials for characterization of the relevant enzymes and factors listed in Table 66.3. The virion RNA polymerase is eukaryotic-like with regard to its size and subunit complexity.⁵² The subunits, ranging from 7 to 147 kD, are encoded by eight viral genes and, except for RPO30 and RPO35, are homologous to those of cellular RNA polymerases, suggesting similar functions.³⁹¹ The RPO30 subunit is approximately 23% identical in sequence to eukaryotic transcription elongation factor SII (TFIIS).

The 94-kD polypeptide known as RAP94, encoded by the *H4L* gene, is associated with RNA polymerase in VACV virions and is specifically required for transcription of early promoter templates.^{6,9,210} RAP94 interacts with VETF, the VACV early transcription factor.⁸⁶⁶ Synthesis of RAP94 occurs late, at the time of virion assembly, consistent with its role as a virion-associated early transcription factor. In contrast, the genes encoding the core RNA polymerase subunits have early promoters because they are also needed for intermediate and late transcription.

Transcriptional activity can be reconstituted *in vitro* with RNA polymerase and VETF, a heterodimer of 82- and 70-kD subunits.^{103,109,271} VETF, like RAP94, is synthesized only at late times after infection. The protein binds to the core region of early promoters and to DNA downstream of the RNA start site, thereby altering the conformation of the DNA.^{105,131} Single nucleotide substitutions in the core sequence of the promoter that decrease transcription also abrogate specific DNA binding.⁸⁷² A DNA-dependent adenosine triphosphatase (ATPase) activity associated with the small subunit of VETF is not required for

promoter binding but is essential for transcription, apparently via a promoter clearance mechanism.^{101,106,424} Complexes of VETF and RNA polymerase have been detected, suggesting that VETF may recruit RNA polymerase to the promoter.^{40,108,423} The elongation complex has a 3' RNase activity that permits resumption of transcription by stalled polymerase.²⁹⁶ The latter RNase activity is similar to one exhibited by eukaryotic RNA polymerase II in the presence of TFIIS, a VACV RPO30 homolog.

A complex of RNA polymerase, RAP94, VETF, capping enzyme (sometimes called VTF when referring to its termination role), and NPH I can accurately terminate as well as initiate transcription on DNA templates containing an early promoter and T5NT sequence.^{108,873} Although RNA polymerase and VETF can reconstitute the transcription initiation and elongation activities, capping enzyme and NPH I are needed to release nascent mRNA containing a U5NU sequence from the transcription complex in an adenosine triphosphate (ATP)-dependent reaction.^{145,146,209,583,698,701} The physical interaction of NPH I with RAP94 may explain the specificity of this termination system for early transcripts.^{494,584} NPH I also serves as a polymerase elongation factor to facilitate read-through of intrinsic pause sites.²⁰⁹

Early viral transcripts made *in vivo* or *in vitro* are capped^{87,822} and polyadenylated³⁷⁵ like eukaryotic mRNAs. RNAs synthesized by virus cores contain a cap I structure that consists of a terminal 7-methylguanosine connected via a triphosphate bridge to a 2'-O-methylribonucleoside. The N⁷-methylguanosine component of the cap is required for mRNA stability and for binding of VACV mRNA to ribosomes,⁵²⁷ whereas ribose methylation may have a role in subverting the activity of type I interferon (IFN).⁸⁸⁶ Capping occurs during transcription when the nascent RNA chains are approximately 30 nucleotides long.^{295,823} The steps in cap formation are (a) removal of the terminal phosphate of the triphosphate end of the nascent RNA to form a pp(5')N-terminus, (b) transfer of a guanosine monophosphate (GMP) residue from guanosine triphosphate (GTP) to form G(5')ppp(5')N-, (c) transfer of a methyl group from S-adenosylmethionine to produce m⁷G(5')ppp(5')N-, and (d) transfer of a second methyl group to form m⁷G(5')ppp(5')Nm. The first three reactions are catalyzed by the virus-encoded 127-kD capping enzyme heterodimer.^{453,454,799}

The fourth step in cap formation, ribose methylation of the penultimate nucleoside, is mediated by a separate viral enzyme.⁵¹ The capping enzyme large subunit forms a covalent lysyl-GMP intermediate.^{542,699} The RNA triphosphatase and guanylyltransferase activities reside in an N-terminal segment of the large subunit,^{293,528,700} whereas a complex of the C-terminal part of the large subunit and the small subunit contains the N⁷-methyltransferase (N⁷-MTase) activity.^{312,450} The nucleoside 2'-MTase is a 39-kD protein that exists as a monomeric species and has an additional role as the VP39 subunit of poly(A) polymerase.⁶⁶² High-resolution x-ray crystal structures of the nucleoside 2'-MTase complexed to its methyl donor and mRNA cap have been obtained.^{319,320} Viral mRNAs synthesized *in vivo* have additional base and ribose methylations that are catalyzed by cellular enzymes.⁸⁷ Phenotypic analysis of a temperature-sensitive mutant in the large subunit of the capping enzyme supports its multifunctional roles.⁶⁸⁷

The enzyme that catalyzes poly(A) tail formation is a heterodimer of virus-encoded 55- and 39-kD subunits called VP55 and VP39, respectively.^{269,511,520} VP55 binds to uridylate

sequences near the end of the RNA chain and catalyzes the processive addition of 30 to 35 adenylate residues before changing to a slow and nonprocessive mechanism.^{208,273,871} VP39 binds poly(A) and stimulates VP55 to semiprocessively add additional adenylate residues.²⁷² Thus, VP39, which is present in an excess over VP55, serves as a processivity factor for the poly(A) polymerase as well as a MTase. The two activities are independent because mutated forms of VP39 that lack MTase retain adenylyltransferase stimulatory activity.^{663,688} Genetic and biochemical studies indicate an additional role of VP39 as an RNA elongation factor for intermediate and late RNA synthesis to be discussed later.^{418,854} The finding that the capping enzyme/termination factor and the ribose MTase/poly(A) polymerase processivity factor function at the 5' and 3' ends of the mRNA is intriguing. The association of such apparently disparate functions in the same enzymes may provide a specific advantage or represent an economical use of proteins.

The minimal components for synthesis of correctly initiated, terminated, capped, and polyadenylated mRNAs were defined by *in vitro* reconstitution assays. However, several additional proteins are needed within the confines of the virus core. These include the DNA topoisomerase,¹⁷⁰ NPH II,²⁸⁶ the H1 serine/tyrosine phosphatase,⁴³⁶ the L4 DNA-RNA-binding protein,⁸³³ and the L3⁶¹⁴ and E8³⁷⁸ proteins of unknown function.

Regulation of Intermediate-Stage Transcription

Amino acid labeling^{514,574} and transcription^{41,803} studies indicated the existence of an intermediate class of genes that are expressed after DNA replication but before expression of the late genes (Fig. 66.8). The rapid decline in intermediate mRNAs results from shutoff of transcription coupled with rapid mRNA turnover. Analysis of some intermediate mRNAs by gel electrophoresis indicated diffuse bands, equal to and longer than the coding regions, suggesting preferred sites of 3' end formation that do not correlate with early gene transcriptional termination signals.⁴¹ The original 5 VACV genes belonging to the intermediate class^{384,803} have been expanded to 53.⁸⁶⁷ Three of the intermediate genes (*A1L*, *A2L*, and *G8R*) encode late-stage transcription factors,³⁸⁴ and others include DNA binding/packaging and core-associated proteins.

The DNA replication requirement for intermediate gene expression may result from the inaccessibility of the genome within the infecting particle to newly synthesized transcription factors. This hypothesis is consistent with transfection experiments showing that DNA isolated from purified virus particles can serve as a template for intermediate and late transcription in the absence of DNA replication.³⁸⁴

Intermediate-Stage Promoters

Mutagenesis of intermediate promoters indicated two important regions: a 14-bp core element separated by 10 or 11 bp from a 4-bp initiator element.^{42,392} The intermediate core resembles that of early promoters in A/T richness but differs in specific sequence. The tetranucleotide TAAA serves as an initiator element of intermediate promoters. A consensus (Fig. 66.9) has been derived from an analysis of the sequences preceding recently identified intermediate ORFs.⁸⁶⁷ Intermediate-stage RNAs are initiated within the AAA triplet of the coding strand, but as discussed later, they contain additional A residues incorporated by a polymerase slippage mechanism.

Enzymes and Factors for Intermediate-Stage Transcription

Intermediate promoter templates can be transcribed by extracts prepared from cells infected with VACV in the presence of an inhibitor of DNA replication.⁸⁰³ Further studies indicated a role for both viral and cellular proteins. The viral proteins include RNA polymerase; the capping enzyme, which acts by a mechanism that does not involve cap formation^{304,802}; VITF-1, which is encoded by the gene for RPO30, a viral RNA polymerase subunit with homology to eukaryotic transcription elongation factor TFIIS⁶³⁵; and VITF-3, a heterodimer composed of polypeptides encoded by the *A8R* and *A23R* genes⁶⁴⁹ (Table 66.6). Unlike the early transcription factor VETF, neither VITF-1 nor VITF-3 has ATPase activities or exhibits demonstrable sequence-specific DNA binding. A cellular component, called VITF-2, was found to be necessary to complement *in vitro* transcription.⁶³⁶ Recently, both natural and recombinant forms of two cellular proteins, Ras-GTPase-activating protein SH3 domain-binding protein (G3BP) and cytoplasmic activation/proliferation-associated protein (p137), which form a complex, were individually shown to fulfill the requirement for VITF-2 in an *in vitro* complementation assay.³⁸⁰ Their role *in vivo* is suggested by the accumulation of both G3BP and p137 at sites of transcription in viral factories (Fig. 66.10). There is evidence from *in vivo* experiments employing RNA interference (RNAi) and dominant negative inhibitors that the cellular TATA-binding protein has a positive role in VACV intermediate and late gene expression and that YY1 has a negative role by binding to promoter and initiator elements, respectively.^{392,393} The reliance on cellular proteins is surprising because POXVs encode their own RNA polymerase and other transcription factors.

Genetic studies provide evidence for virus-encoded positive and negative regulators of intermediate and/or late transcription elongation. To summarize an interesting story,^{155,471,553} mutations in the *A18R* gene increase transcriptional read-through of downstream gene sequences, whereas mutations of the *G2R* gene decrease mRNA length and *G2R* mutants can rescue *A18R* mut

ants.^{79,157,858} Physical interactions between the proteins encoded by *G2R*, *A18R*, and *H5R* (a late transcription factor) were demonstrated by a variety of methods.^{80,463} Additional biochemical studies suggest that the *A18R* helicase is a transcript release factor and acts in conjunction with an unidentified cellular protein.⁴¹⁰ Genetic approaches also led to the identification of the product of the *J3R* gene, which also serves as the cap 2'-O-MTase and as a subunit of the poly(A) polymerase, as an mRNA elongation factor.^{418,854}

Regulation of Late-Stage Transcription

The transcription of late genes quickly follows that of intermediate genes and persists till the end of the virus life cycle (Fig. 66.8). The half-life of late mRNAs has been estimated to be 30 minutes or less,^{546,668} emphasizing the need for continued high-level transcription. A recent study distinguished intermediate and late genes and identified 38 belong to the latter class and encoding many morphogenesis and mature virion membrane proteins, including those involved in entry, in addition to early transcription factors.⁸⁶⁷ Although distributed throughout the genome, the late-stage genes cluster in the central region (Fig. 66.4).

Late-Stage Promoters and RNA Processing Signal

Late-stage promoters consist of a core sequence of about 20 bp with some consecutive T residues, separated by a region of about 6 bp from a highly conserved TAAAT element within which transcription initiates.¹⁸⁵ A synthetic promoter with exclusively T residues forming the core sequence was stronger than natural late promoters tested, and any mutations of TAAAT severely decreased transcription. A consensus promoter (Fig. 66.9) derived from the sequence upstream of late ORFs is consistent with the mutational analysis.⁸⁶⁷ A G or A usually follows the late promoter TAAAT sequence: in the former case, the TAAATG transcription initiation sequence and the ATG translation initiation codon overlap. The seeming absence of an untranslated

FIGURE 66.10. Localization of translation initiation factors within virus factories. **A:** Uninfected (Un) and vaccinia virus (VACV)-infected (In) HeLa cells were stained with antibody to the elF4G translation factor (green) and to DNA with DAPI (blue). The infected cells were also stained with antibody to cellular G3BP, which co-localizes with viral RNA in the factory. F, viral factory. **B:** Same as panel **A** except that antibody to the elF4E translation initiation factor (green) was used instead of antibody to elF4G. (From Katsafanas GC, Moss B. Colocalization of transcription and translation within cytoplasmic poxvirus factories coordinates viral expression and subjugates host functions. *Cell Host Microbe* 2007;2:221–228.)

RNA leader in this situation was puzzling, until it was found that late mRNAs have a 5' capped, heterogeneous-length, poly(A) leader sequence formed by RNA polymerase slippage.^{567,667} Poly(A) leaders are also present on mRNAs of certain early genes that have a TAAAT initiation site^{7,356,864} as well as on intermediate mRNAs,⁴¹ suggesting that slippage on an AAA sequence is an intrinsic property of the viral RNA polymerase. The 5' poly(A) may facilitate stability and translation.^{72,691}

Most postreplicative transcripts are long and heterogeneous and lack defined 3' ends.^{159,445} The early termination signal is not recognized even though T5NT is frequently present within the coding region of postreplicative genes. Terminal heterogeneity, combined with transcription from both DNA strands, causes overlapping of transcripts, explaining their ability to self-anneal or anneal with early transcripts to form ribonuclease-resistant hybrids.^{89,152,797} Possibly, the VACV-encoded double-stranded RNA-binding protein^{133a} or RNA helicase⁶⁹⁷ prevents deleterious effects of the double-stranded RNA. Alternatively, the 5' poly(A) leader could compensate for the complementary RNA by providing a single-stranded binding site for initiation factors and the 40s ribosomal subunit, which would then move unimpeded by antisense RNA to the first AUG where ribosome assembly and translation occur.

Exceptions to the general 3' heterogeneity of late mRNAs occur.²⁵ The CPXV late mRNA encoding the A-type inclusion protein has a 3' end corresponding to a precise site in the DNA template. The DNA sequence at this position encodes an RNA *cis*-acting signal for RNA 3' end formation that can function independently of either the nature of the promoter or the RNA

polymerase responsible for generating the primary RNA.³²⁷ Cleavage also generates the 3' end of F17R transcripts,¹⁶⁷ and endoribonuclease activity associated with the product of the *H5R* gene can cleave this RNA,¹⁶⁸ which is then polyadenylated. The number of late mRNAs that are processed in this manner remains to be determined. Therefore, POXVs employ at least two mechanisms of RNA 3' end formation. The first, operative at early times in viral replication, terminates transcription downstream of an RNA signal, whereas the second, operative at late times, involves RNA site-specific cleavage.

Enzymes and Factors for Late-Stage Transcription

The viral RNA polymerase catalyzes late mRNA synthesis in conjunction with specific factors. Late transcription factors (Table 66.6) were identified by the systematic screening of cloned viral DNA fragments: open reading frames A1L, A2L, and G8R were necessary and sufficient for transactivation of a transfected late promoter reporter gene in VACV-infected cells that were blocked in DNA replication.³⁸⁴ An intermediate promoter regulates each of these late transcription factor genes, which is consistent with a cascade model of regulation. *In vitro* studies confirmed that the products of the *G8R*, *A1L*, and *A2L* genes are VACV late transcription factors,^{342,386,566,851,852} and they have been named VLTF-1, VLTF-2, and VLTF-3, respectively. Temperature-sensitive and repressible mutations of A1L and G8R, respectively, block late gene expression under non-permissive conditions.^{126,884} Both A1 and A2 can bind zinc,³⁸⁵ and yeast two-hybrid studies indicate interactions between G8 with itself and with A1.⁴⁶³ Computational analysis suggests

that G8 has a PCNA-like sliding clamp motif.¹⁷⁴ *In vitro* studies indicated that the product of the early *H5R* gene, named VLTF-4, stimulated late transcription severalfold,⁴⁰¹ and interactions between H5 and other late transcription factors have been described.²⁰⁵ H5 also appears to have a role in transcript elongation.⁸⁰ *In vitro* transcription assays suggest a role for a host factor originally called VLTF-X and shown to consist of the heterogeneous nuclear ribonucleoproteins A2/B1 and RBM3.^{292,853} As noted above, there is evidence that the cellular TATA-binding protein has a positive role in VACV intermediate and late gene expression and that YY1 has a negative role by binding to promoter and initiator elements.^{392,393}

DNA REPLICATION

General Features

POXV DNA replication takes place in the cytoplasm and can occur even in enucleated cells.^{575,593} Discrete cytoplasmic foci of replication, termed *factory areas*, are discerned by light and electron microscopic autoradiography.^{121,302} Factories visualized with a dye that stains double-stranded DNA are shown in Figure 66.10 (which also shows the redistribution of translation initiation factors discussed later and the localization of the G3BP, which is involved in intermediate transcription as discussed earlier). Each factory can be initiated by a single virion, although factories merge together with time.^{379,429} Replicating DNA may be associated with endoplasmic reticulum (ER) membranes.⁶⁶⁵ The time of onset of DNA synthesis varies with different members of the POXV family and to some extent with the multiplicity of infection and cell type. DNA replication begins 1 to 2 hours after infection of growing cells synchronously infected with VACV and results in the generation of about 10,000 genome copies per cell, of which half are ultimately packaged into virions.^{370,643} Studies depending on thymidine incorporation instead of hybridization for DNA quantification generally underestimated the length of the replication period, possibly because of a decline in the activity of the viral thymidine kinase (TK) used for incorporation of the radioactive precursor via the salvage pathway.

Efforts to locate a specific POXV origin of replication using a plasmid assay in transfected cells were unsuccessful; surprisingly, any circular DNA replicates in cells infected with Shope fibroma virus (SFV)²⁰³ or VACV.⁴⁸⁷ Further studies demonstrated that origin-independent plasmid replication occurs in virus factory areas and requires each protein needed for genome replication, confirming the specificity of this activity.¹⁹³ The absence of any stimulatory effect of VACV DNA sequences led to speculation that POXVs, unlike nuclear DNA viruses, do not require specific replication origins. Using another transfection assay, in which the template was a linear DNA molecule containing VACV hairpin ends, a specific enhancing effect of the terminal 200 bp of the viral genome was found.²²⁶ The mechanism of enhancement is uncertain, however, and this region contains the concatemer resolution sequence (to be described later).

DNA Replication Models

The unique terminal structure of the POXV genome,⁵³ evidence that nicking and initiation occur near the ends of the molecule,^{588,590} and the presence of junction fragments^{54,522} and high-molecular-weight DNA^{201,486} suggested a model similar

FIGURE 66.11. Self-priming model of poxvirus DNA replication. F and S within the hairpin loops refer to the fast and slow electrophoretic mobilities of DNA fragments containing inverted and complementary hairpin sequences as shown in Figure 66.3. Dashed lines indicate newly synthesized DNA with arrowheads at the 3' OH ends. Complementary sequences are depicted by upper- and lowercase letters. The resolution site (res) within the concatemer junction is indicated. (Adapted from Moss B, Winters E, Jones EV. Replication of vaccinia virus. In: Cozzarelli N, ed. *Mechanics of DNA Replication and Recombination*. New York: A. Liss, 1983:449–461.)

to the rolling hairpin strand displacement mechanism proposed for replication of single-stranded parvovirus DNA.⁷⁵⁸ As depicted in Figure 66.11, a hypothetical nick occurring at one or both ends of the genome provides a free 3' end for priming replication. The replicated DNA strand then folds back on itself and the replication complex copies the remainder of the genome. Concatemer junctions form after replication through the hairpin; very large branched concatemers can arise by initiating new rounds of replication before resolution occurs. After the onset of late-stage transcription, unit-length genomes are resolved and the incompletely base-paired terminal loops, with inverted and complementary sequences, are regenerated. Despite the attractiveness of this model, neither the site

of nicking nor an essential nicking enzyme needed to initiate DNA replication has been identified.

A more conventional model posits RNA priming and semidiscontinuous DNA synthesis at replication forks. Early reports of VACV DNA covalently linked to RNA and the chasing of short DNA into larger molecules suggested lagging strand synthesis.^{238–240,589} A major difficulty with the discontinuous model, however, had been that a virus-encoded RNA primase had not been identified and the virus-encoded DNA ligase was not essential. However, as described later, a VACV-encoded primase was recently discovered and it was found that a cellular DNA ligase substitutes for the viral ligase in the absence of the latter. In addition, recombination-dependent DNA replication involving invasion of duplex DNA by the 3' OH end of single-stranded DNA as described for phage T4⁴⁰³ could account for branched DNA molecules. The aforementioned models are not mutually exclusive and it is possible that POXVs use multiple mechanisms to achieve replication of their large genomes.

Enzymes Involved in DNA Precursor Metabolism

Many POXVs encode enzymes involved in the synthesis of deoxyribonucleotides, evidently to enhance DNA replication in cells with suboptimal precursor pools, whereas others lack some or all of these enzymes. In OPXVs, these enzymes include a TK,^{39,329} thymidylate kinase,⁷¹³ ribonucleotide reductase,^{705,761} and deoxyuridine triphosphatase (dUTPase).¹⁰² In addition, there is an incomplete guanylate kinase, raising the possibility that an intact form might be found in some other POXV.⁷¹² Leporipoxviruses are missing genes encoding the large subunit of ribonucleotide reductase, thymidylate kinase, and remnants of the guanylate kinase,^{122,835} and MOCV is missing all of them, perhaps contributing to its limited host range.⁶⁷⁴ FWPV encodes a protein related to human deoxycytidine kinase that is not present in the other POXVs.³⁹⁶ Entomopoxvirus *Melanoplus sanguinipes* lacks all of the previously described POXV genes involved in nucleotide metabolism but has a thymidylate synthetase homolog.³ However, a homologous TK gene is present in other entomopoxviruses.^{288,443}

The TKs encoded by POXVs are 20 to 25 kD and related in sequence to corresponding eukaryotic enzymes (35% to 70% amino acid identity) but not to the pyrimidine kinase of herpesviruses. The structure of VACV TK is very similar to human TK, but there are subtle differences in the association with deoxythymidine triphosphate (dTTP) that might be exploited for antivirals.²³³ The TK gene is regulated by an early promoter, as befits its role in increasing precursors for DNA replication.⁸²⁴ The VACV enzyme exists as a tetramer, has ATP and Mg²⁺ binding domains, and is susceptible to feedback inhibition by deoxythymidine diphosphate (dTDP) or dTTP.⁸¹ Although the TK gene is not required for virus growth in tissue culture cells, deletion mutants are severely attenuated *in vivo*.¹¹³

Thymidylate kinase catalyzes the next step in thymidine monophosphate (TMP) metabolism. The VACV gene encodes a 23-kD protein that can complement *Saccharomyces cerevisiae* mutants deficient in the homologous enzyme.³⁴³ The protein is expressed early in infection and is not required for virus replication in tissue culture. VACV thymidylate kinase has a 42% identity with its human homolog but differs in substantial ways and has broader substrate specificity.^{31,120}

The synthesis of ribonucleotide reductase, an enzyme that converts ribonucleoside diphosphates to deoxyribonucleoside

diphosphates, is induced soon after VACV infection.⁷⁰⁷ The small catalytic subunit and the large regulatory subunit closely resemble their eukaryotic counterparts structurally (70% to 80% identity) and functionally.^{328,706} Catalytic activity is inhibited by hydroxyurea preventing DNA replication, and drug-resistant mutants generate direct tandem repeats of the gene encoding the catalytic subunit.⁷⁰⁹ Mutation of the large subunit prevents induced ribonucleotide reductase activity in tissue culture cells without affecting replication.¹³⁹ However, the mutant virus was mildly attenuated in a mouse model. In contrast to OPXVs, many chordopoxviruses only encode the large subunit, which complexes with the cellular small subunit to form active ribonucleotide reductase.²⁶⁰

The hydrolysis of deoxyuridine triphosphate (dUTP) by the VACV dUTPase provides deoxyuridine monophosphate (dUMP), an intermediate in the biosynthesis of TTP, and might also minimize dUTP incorporation into DNA.¹⁰² The protein is synthesized early in infection⁷⁰⁸ and is nonessential for virus replication in dividing cells.⁵⁷⁹ The dUTPase is more important in quiescent cells, particularly in the absence of the viral uracil DNA glycosylase (UDG).¹⁹² The structure of VACV dUTPase is very similar to the human homolog, although there are subtle differences that might be exploited in drug design.⁶⁴⁴

Viral Proteins Involved in DNA Replication

Several complementation groups of temperature-sensitive (ts) mutants that express VACV early proteins are impaired in DNA synthesis,⁴¹¹ and multiple proteins constitute the replication complex. One complementation group contains mutations in the DNA polymerase, which has a mass of about 110 kD, an associated 3' exonuclease activity, and homology with other eukaryotic and viral DNA polymerases.^{132,229,464} Certain codon substitutions confer resistance to inhibitors of DNA synthesis, providing information regarding the active site of the polymerase.^{199,229,755,756,771}

A second DNA[−] complementation group maps to the *D5R* gene, which encodes a 90-kD protein with a nucleic acid-independent nucleoside triphosphatase activity.^{243,244,245,638} A motif present in the archaeo-eukaryotic primase superfamily is present in the N-terminal domain of D5 and its orthologs,³⁶² and primase activity has been demonstrated.^{191,195} Moreover, mutations of D5 in either the nucleoside triphosphatase (NTPase)⁹⁵ or the primase¹⁹¹ active site are unable to complement a conditional lethal ts mutant.

A third DNA[−] complementation group maps to the B1R ORF, which encodes a 35-kD serine/threonine protein kinase that is expressed early in infection and packaged in virions.^{49,428,612} Human homologs of B1 can complement the replication defect of a ts VACV mutant defective in B1 kinase activity.^{96,537,540} A recent discovery is that a cellular cytoplasmic protein called barrier to autointegration factor, or BAF, acts as a potent inhibitor of POXV DNA replication unless its DNA-binding activity is blocked by B1-mediated phosphorylation.^{541,832} This activity of the B1 kinase can explain its requirement for VACV DNA replication. The B1 kinase may have additional substrates involved in immune defense.^{647,648} An early protein encoded by the *H5R* gene is a substrate for the B1 kinase,⁶⁶ and interactions between these proteins was demonstrated by the yeast two-hybrid system.⁴⁶³ H5 appears to be a multifunctional protein with roles in DNA replication, transcription, mRNA processing, and morphogenesis.^{80,162,168,169,401}

A fourth VACV ts mutant impaired in DNA replication maps to the D4R ORF.⁴⁸⁹ A mutant with a deleted *D4R* gene could be propagated in a transfected cell line stably transfected with D4R.³²³ Both the D4R ORF and its SFV homolog encode functional uracil DNA glycosylases (UDGs).^{740,788} Because these enzymes function in DNA repair by removing uracil residues that have been introduced into DNA, either through misincorporation of dUTP or through the deamination of cytosine, a DNA⁻ phenotype was surprising. However, mutagenesis studies demonstrated that the requirement for UDG is independent of its glycosylase activity, suggesting that it functioned as part of the replication complex.¹⁹⁴ Nevertheless, VACV mutants with enzymatically inactive UDG are attenuated in mice, indicating that the repair function is beneficial, consistent with the preservation of the catalytic site in all POXV orthologs. The sequence identity of POXV UDG with non-POXV homologs is only about 20% and differs in secondary and tertiary structure.⁶⁶⁴

A role for the VACV 49-kD A20 protein, for which non-poxvirus homologs could not be found, was first suggested by a yeast two-hybrid analysis that demonstrated an interaction with the DNA replication proteins D4 and D5 as well as H5.⁴⁶³ Additional yeast two-hybrid studies demonstrated that non-overlapping regions of A20 bind D4, D5, and H5, suggesting that these proteins can interact simultaneously to form a multicomponent complex.³⁵⁹ The interaction of these proteins in infected cells was confirmed by co-immunoprecipitation.³⁵⁹ A role for A20 in VACV DNA replication was shown by targeted mutagenesis^{360,595} and evidence that the complex of A20 and D4 with DNA polymerase imparts processivity.⁷³⁴

The VACV *I3L* gene encodes a 34-kD phosphoprotein that is expressed early in infection, forms octameric complexes on single-stranded DNA,^{183,623,774} and is found in punctate cytoplasmic inclusions containing parental DNA.^{221,825} The inability to isolate a deletion mutant suggests that it is essential for VACV replication.⁶²³

VACV encodes a functional ATP-dependent DNA ligase that is not essential for replication in tissue culture, although it imparts sensitivity to DNA damaging agents and is important for virulence.^{153,387} The ability of VACV to replicate in the absence of the viral DNA ligase depends on cellular DNA ligase I, which is recruited to the viral DNA factories in the cytoplasm.⁵⁵⁸ Thus, viral or cellular ligase activity appears to be required for VACV replication. Furthermore, replication of ligase-deficient VACV was greatly reduced and delayed in resting primary cells, correlating with initial low levels of ligase I and subsequent viral induction and localization of ligase I in virus factories.⁵⁵⁸ By encoding its own ligase, VACV can “jump-start” DNA synthesis in resting cells and enhance replication.

Photolyases, which protect DNA from ultraviolet radiation by excision of cyclobutane pyrimidine dimers, are encoded by avipoxviruses and leporipoxviruses as well as entomopoxviruses.^{71,533,730,731} This enzyme is likely important for POXVs that are transmitted through the environment rather than from animal to animal.

Concatemer Resolution

The replication of the POXV genome involves the formation of concatemers and their resolution into unit-length molecules.^{54,522} The concatemer junction consists of a precise duplex copy of the hairpin loop present at the ends of mature DNA

genomes.⁴⁸³ Circular plasmids containing VACV⁴⁸⁵ or SFV²⁰⁴ concatemer junctions are converted into linear molecules with hairpin termini when transfected into POXV-infected cells. Using this assay, the structural and sequence requirements for resolution of concatemer junctions were determined by site-directed mutagenesis.^{202,467,482,484} The minimal requirement for resolution is two copies of the sequence T₆-N₇₋₉-T/C-A₃-T/A present in an inverted repeat orientation on either side of an extended double-stranded copy of the hairpin loop. Interestingly, the resolution sequence encompasses a functional promoter, suggesting that resolution may be linked to transcription.^{334,739} The sequence of the intervening region, destined to form the hairpin loop, is not highly conserved but must be palindromic and less than 200 bp long.

Concatemer resolution occurs rapidly, as junctions do not accumulate unless postreplicative gene expression is inhibited.^{201,486} DNA incapable of entering a pulse-field gel also accumulates under the latter conditions, suggesting multiply branched DNA molecules. Studies with drugs and mutants indicate that concatemer resolution occurs independently of virus assembly.

The concatemer junction contains an inverted repetition, which in supercoiled plasmids can form a cruciform structure resembling a four-way Holliday junction (HJ) recombination intermediate.^{213,483} This suggested that the putative concatemer-resolving enzyme would be an HJ resolvase. Bioinformatic analyses led to the discovery of motifs and structural elements that are critical for activity of *Escherichia coli* RuvC HJ resolvase in ORFs that are conserved in all POXV genomes.²⁶² Moreover, the RuvC homolog encoded by the VACV *A22R* gene was expressed as a recombinant protein in *E. coli* and found to specifically cleave HJs.²⁶² Like RuvC, the A22 protein is a dimer in solution and when bound to HJ structures, but exhibits less cleavage sequence specificity.²⁶⁴ The quaternary structure and cleavage specificity of the HJ have been explored extensively.^{165,264} A VACV-inducible A22 null mutant was defective in processing concatemers into unit-length genomes with hairpin ends under nonpermissive conditions, indicating that the enzyme is required for resolution, although additional proteins may also be involved in determining site specificity.²⁶³

Type I DNA topoisomerases form a covalent link with DNA and relieve supercoils during replication, transcription, recombination, and other activities. POXVs encode a type I topoisomerase that has served as a model for this class of enzymes.^{686,702,862} The POXV topoisomerase is unusual in that it exhibits some sequence specificity.⁶⁹⁶ *In vitro*, the topoisomerase can carry out a variety of reactions including strand transfer, transesterification, recombination, and cleavage and ligation of a variety of DNA structures *in vitro* including an HJ.^{554,672} The late promoter of the topoisomerase gene is consistent with a role in early transcription or DNA processing *in vivo*. Characterization of a VACV topoisomerase deletion mutant that forms very small plaques indicated that the enzyme participates in early transcription within the virus core and that subsequent DNA synthesis and concatemer resolution occurred.¹⁷⁰

Homologous Recombination

Recombination occurs actively within POXV-infected cells²⁴⁹ and has apparently occurred naturally between SFV, which produces benign fibromas in rabbits, and myxoma virus (MYXV), the agent of myxomatosis, to form malignant rabbit fibroma

virus,⁸⁶ and between individual capripoxviruses.²⁷⁰ Recombination between the terminal sequences of POXV DNA may explain variations in the number of tandem repeats as well as translocations and mirror image deletions.^{237,466,515,523} Most extraordinarily, field and vaccine strains of FWPV carry a near-full-length and apparently infectious integrated avian retrovirus genome.³¹⁰

Recombination can also occur between viral genomic DNA and transfected subgenomic DNA fragments, and this has been exploited to map and construct mutations and to insert genes for expression.⁵⁰⁹ Viral genomes rapidly eliminate direct repeats with the formation of intra- and intermolecular recombination products.⁴⁵ Single- and double-crossover products resulting from recombination between transfected plasmids and viral genomes⁷²⁹ and inter- and intramolecular plasmid or bacteriophage DNA recombinants^{242,561} have been detected in POXV-infected cells.

The mechanism of recombination has not been fully elucidated. Recombination does not require postreplicative gene products, and there appears to be a strong connection between recombination and replication.^{481,834} There is evidence that the DNA polymerase participates directly in recombination and that the 3' exonuclease and DNA joining activities are involved.^{259,299,300} The protein encoded by the *G5R* gene, which is conserved in all POXVs and expressed early in infection, belongs to the FEN1 family of *exo-/endonucleases*.^{173,361} A VACV G5 deletion mutant is severely impaired and the yield of infectious virus is reduced by two orders of magnitude.⁶⁷⁵ The mutant virions contain an apparently normal complement of proteins but appear spherical rather than brick shaped and contain little or no DNA. Although the amount of viral DNA produced in the absence of G5 is similar to that made by wild-type virus, the mean size is approximately one-fourth of the genome length. Experiments with transfected plasmids show that G5 was required for double-strand break repair by homologous recombination, suggesting a similar role during VACV genome replication.⁶⁷⁵ Double-strand breaks commonly occur at replication forks, consistent with the semidiscontinuous model of POXV DNA replication.

The chordopoxviruses, except for avipoxviruses, encode homologs of serine recombinases.¹ However, only the crocodile POXV contains all amino acids that make up the catalytic active site, and deletion of the VACV F16 homolog had no effect on replication in cultured cells.⁶⁷⁶

VIRION ASSEMBLY

Overview

The assembly of VACV is outlined within Figure 66.7, and a thin-section transmission electron microscopic image of a cell infected with VACV and enlarged pictures of virions at successive stages of assembly and egress are shown in Figures 66.12 and 66.13, respectively. The initial stages of virion assembly occur in the circumscribed, granular, electron-dense areas of the cytoplasm containing viral DNA called virus factories. The first morphologically distinct structures are crescent membranes and circular immature virions (IVs) that represent sections through cupules and spheres. These structures consist of a membrane with spicules on the convex surface and granular material in the concavity. Deep-etch electron microscopy revealed that the

FIGURE 66.12. Transmission electron microscopy of cell infected with vaccinia virus (VACV). N, cell nucleus; c, viral crescent; IV, immature virion; nu, DNA nucleoid within IV; MV, mature virion; WV, wrapped virion; EV, extracellular enveloped virion. (Image kindly provided by A. Weisberg.)

spicule layer is actually a honeycomb lattice viewed on edge (Fig. 66.14).^{311,750} A dense nucleoprotein mass containing the genome enters the immature envelope (Fig. 66.13) before it is completely sealed,⁵⁰¹ apparently in association with a membrane.⁶⁶⁵ Next, the spherical IV is converted to an oval or brick-shaped particle, with a concomitant loss of the lattice scaffold and internal reorganization (Fig. 66.13). The MV is the most abundant infectious form of VACV, although it can only be released by cell lysis. VACV assembly and morphogenesis is the subject of a recent review.¹⁵⁶

Formation of the Crescent and IV Membrane

The mechanism of IV formation is incompletely understood. Microscopic images showing crescents open to the cytoplasm and with no apparent connection to cellular organelles led to the idea that the viral membrane forms *de novo*.¹⁷⁷ Such an open architecture, however, goes against current thoughts that stable membranes must have sealed ends and arise from pre-existing membranes. An alternative hypothesis proposed that the IV membrane is a flattened cisterna derived from a cellular organelle and hence is a double membrane. While some images seem to support two membranes,^{283,620,718} others clearly show a single bilayer with a spicule or lattice protein coating.^{177,188,284,303,322,501} and the group originally promoting a double-membrane has accepted the single-membrane structure.¹⁴³ Moreover, freeze fracture studies provide no evidence for more than one bilayer.³¹¹

In the absence of unambiguous images depicting crescent membranes in continuity with membranes of cellular organelles, other approaches to determine their origin have been pursued. The evidence seems to favor the ER, although the intermediate compartment between the ER and Golgi apparatus (ERGIC) has been suggested. Antibodies to viral membrane proteins co-localize with markers of the ERGIC^{404,620,642,718} and an

FIGURE 66.13. Stages of vaccinia virus (VACV) morphogenesis. Infected cells were cryosectioned and viewed by transmission electron microscopy. In the panels showing crescent stage (C), immature virion (IV), immature virion with nucleoid (Nu), and mature virion (MV), the arrow points to the single outer membrane. Note the presence of the thick “spicule layer” comprising the D13 lattice on the outside of the crescent and IVs. In the panel showing the wrapped virion (WV), the inner arrow points to the MV membrane and the two outer arrows to the double wrapping membrane. In the panel showing the extracellular enveloped virion (EV), one arrow points to the outer wrapping membrane that has fused with the plasma membrane; the other arrows point to the MV membrane and remaining EV wrapper. (Courtesy of A. Weisberg.)

inhibitory effect of the protein kinase inhibitor H89 on viral morphogenesis was interpreted as due to blocking ER exit.⁵⁹⁶ However, blockade of the COPII ER exit pathway by dominant negative inhibitors of the Sar1 GTPase³⁴⁵ and the drug brefeldin A⁷⁸² have no effect on formation of IVs or MVs, suggesting that the ERGIC is not a necessary source of the IV membrane. In addition, MV membrane proteins have been shown to associate with the ER although the opposite (i.e., association of ER proteins with IV membranes) has not,³⁴⁸ and none of the viral proteins incorporated into purified MVs have a signature of ER translocation, such as signal peptide cleavage or glycosylation. However, a heterologous signal peptide fused to the N-terminal region of a VACV membrane protein was cleaved and the truncated protein localized in IVs and MVs, providing evidence for a functional pathway between the ER and viral membranes.³⁴⁸

Several proteins required for the formation of crescents and IVs have been identified. The formation of masses of electron-dense “viroplasm” resembling the interior of IVs with few or no crescent membranes represents a characteristic phenotype of cells infected with F10 kinase,^{770,811} H5,²⁰⁷ G5,¹⁷¹ A11,⁶¹⁶ H7,⁶⁵⁵ and L2⁴⁵⁸ conditional lethal mutants. H5 and G5 have other roles, so their action in crescent formation may be indirect. In contrast to the others, L2 is made early in infection, has a

transmembrane domain, associates predominantly with the ER, and can be found near the growing edge of crescents.⁴⁵⁹ F10 phosphorylates the A14 and A17 IV membrane proteins^{75,211} and the kinase activity is required for its function in morphogenesis.^{596,751} A11 is phosphorylated but not by the F10 kinase.⁶¹⁶

When synthesis of the A17 or A14 protein is repressed, small vesicles accumulate, though they differ in appearance, and crescent formation is reduced or abrogated.^{628,629,772,847} The related phenotypes are consistent with evidence that the two proteins interact with each other.^{75,480,628} Whether these vesicles represent true intermediates that accumulate due to the absence of A17 or A14 or represent aberrant structures is unknown.

In the presence of the antibiotic rifampicin, irregular viral membranes that lack the honeycomb lattice accumulate (Fig. 66.15).^{512,529} Within minutes after removal of the drug, the single-membrane bilayer becomes coated with the protein forming the honeycomb and assumes a crescent shape even in the presence of inhibitors of RNA or protein synthesis, suggesting that rifampicin directly interferes with assembly.²⁸⁴ The gene responsible for resistance of mutant viruses to rifampicin was mapped to the D13L ORE,^{43,135,757b} which encodes a 65-kD protein that rapidly associates with the rifampicin membranes after drug removal.^{490,719,795} When expression of the D13 is repressed, morphogenesis of the viral envelope is blocked at

FIGURE 66.14. Deep-etch electron microscopy of immunogold-labeled immature virions (IVs). Thawed cryosections of IVs were labeled with antibody to the D13 scaffold protein and protein A conjugated to gold spheres and then were processed for deep-etch electron microscopy. IVs that were uncut or cut at various depths off their equator are shown. The gold particles look white as a result of contrast reversal. (From Szajner P, Weisberg AS, Lebowitz J, et al. External scaffold of spherical immature poxvirus particles is made of protein trimers, forming a honeycomb lattice. *J Cell Biol* 2005;170:971–981.)

the same stage as occurs with rifampicin.⁸⁸² The 65-kD protein forms trimers that assemble to form the honeycomb lattice scaffold, which gives the IVs a spherical shape.⁷⁵⁰ Deep-etch electron microscopy of immunogold-labeled sections at various depths through IVs is shown in Figure 66.14. Note that this technique only labels the cut surfaces of the IVs. The D13 protein interacts with the N-terminal region of A17 to form the scaffold.⁷⁸ The retention of a capsid-like structure around the immature form of POXVs suggests that their morphogenesis, like embryogenesis, recapitulates evolution to the present MV form.⁷⁵⁰ Structural studies confirm the predicted similarity of D13 with the capsids of other viruses and phage.^{37,350,351}

Association of Core Proteins With IVs

The dense viroplasm that is engulfed during the extension of the crescent into the IV contains unprocessed core proteins. Insight into the association of the core proteins with the crescent membrane has been obtained through use of conditional-lethal VACV mutants. Seven core proteins, A15, A30, D2, D3, F10, G7, and J1, are each required for the association of crescent membranes with the granular viroplasm.^{142,748,749,752–754} These seven proteins form a complex that is presumably linked to one or more membrane proteins. Similar phenotypes occur when expression of the F17 (also called F18), A10, and E6 core proteins are repressed,^{94,307,615,624,883} and the former has also been found in association with the complex.⁸³¹

FIGURE 66.15. Electron micrographs of thin sections of cell infected with vaccinia virus (VACV) in the presence of rifampicin. Upper panel: HeLa cells were fixed and sectioned at 8 hours after infection in the presence of rifampicin. Lower panel: Cells were fixed and sectioned at 10 minutes after removal of rifampicin. Note the thin uncoated single membrane bilayer loop connecting the more rigid crescent-like membranes that have acquired the "spicule" layer. (From Grimley PM, Rosenblum EN, Mims SJ, et al. Interruption by rifampin of an early stage in vaccinia virus morphogenesis: accumulation of membranes which are precursors of virus envelopes. *J Virol* 1970;6:519–533.)

Genome Packaging

Electron micrographs show DNA nucleoids entering IVs before their complete closure.⁵⁰⁰ When morphogenesis is interrupted at a pre-IV stage, the viral DNA concatemers are processed normally and mature DNA accumulates in large crystalloid structures.²⁸⁴ The ultrastructure of these crystalloids is similar to that of nucleoids in normal IVs. Although concatemer resolution occurs in the absence of viral morphogenesis, the opposite is not true; for example, DNA processing is required for morphogenesis.²⁶³ A DNA packaging role for the protein encoded by the *A32L* gene was predicted because of sequence similarity to the products of gene *I* of filamentous single-strand DNA bacteriophages and to the *IVa2* gene of adenovirus, both of which are ATPases involved in DNA packaging.³⁹⁷ This hypothesis was confirmed by the finding that repression of A32 synthesis blocked VACV genome packaging.¹³⁰ DNA packaging also fails to occur under nonpermissive conditions in cells infected with a ts mutant that mapped to the I6 telomere-binding protein

of VACV.^{206,287} Mutation of a second telomere-binding protein encoded by the *I1* gene, however, causes a defect at a later stage of morphogenesis.^{287,390} Conditional lethal mutants of the A13 protein, which is a component of the virion membrane, also display a defect in genome packaging, and DNA crystalloids associated with membrane accumulate.⁷⁸⁴ Exactly how the membrane protein, telomere-binding protein, and ATPase enable genome entry is unknown.

Packaging of the Transcription Apparatus

Like other core proteins, the transcription enzymes and factors are enclosed within the IVs. Morphologically normal but non-infectious virus particles form when synthesis of RAP94, the RNA polymerase-associated protein required for transcription of early genes, is repressed.⁸⁸¹ These particles contain structural proteins as well as the early transcription factor VETF, but lack the viral RNA polymerase, poly(A) polymerase, capping enzyme, topoisomerase, NPH I, and NPH II. Such a specific effect could be explained by the presence of a multienzyme complex that associates with promoter-bound VETF through RAP94. Physical association of RAP94 with NPH I⁴⁹⁴ and VETF⁸⁶⁶ has been demonstrated. A reduced amount of RNA polymerase in virions formed with a ts mutation in VETF⁸⁸¹ is also consistent with the latter model. Repression of synthesis of VETF, however, leads to a more severe defect with accumulation of immature virus particles.^{337,338}

Removal of the D13 Scaffold From IVs

The remarkable transition of the spherical IV to the more compact and barrel-shaped MV involves loss of the D13 scaffold (Fig. 66.13).^{311,497,719} Disassembly of the D13 scaffold correlates with processing of A17 by the I7 protease; when I7 expression is repressed, D13 is retained on aberrant virus particles.⁷⁸ Disassembly of the scaffold and transition to MVs fail to occur when expression of A9 is repressed⁸⁶⁹ and with a ts A6L mutant at the nonpermissive temperature.⁴⁷⁵ There is also some accumulation of IVs and delayed formation of MVs when the *H3L* gene is deleted.^{172,426}

Proteolytic Processing of Virion Proteins

At least one membrane protein (A17) and five core proteins (A3, A10, A12, G7, L4) undergo proteolytic processing. Processing of A17 depends on formation of the membrane component of the IV,⁶¹⁶ whereas processing of core proteins fails to occur if a later step in morphogenesis is blocked.^{381,510} In each case, cleavage occurs at the consensus sequence AG↓X.⁷⁹⁴ The protease responsible for cleavage of the aforementioned proteins appears to be the product of the *I7L* gene based on the phenotype of ts mutants^{374,492} and conserved cysteine protease active site mutants.^{23,115,116} Nevertheless, I7 protease activity has not yet been demonstrated *in vitro*. The product of the *G1L* gene contains a motif HXXEH that is found in some metalloproteases. Conditional lethal G1 mutants are blocked in morphogenesis, but processing of the known membrane and core proteins is not affected.^{24,306} Nevertheless, mutagenesis of the putative active site abrogates the ability of G1 to complement a null mutant. The G1 protein itself appears to be proteolytically processed, and one hypothesis is that it mediates self-cleavage.

Intramolecular Disulfide Bond Pathway

The cytoplasmic domains of some MV membrane proteins contain intramolecular disulfide bonds. Because disulfide bonds usually form in the ER, this raised the possibility that POXVs encode novel oxidoreductases. Indeed, the three viral proteins A2.5, E10, and G4 form a unique cytoplasmic disulfide bond pathway.^{673,681,682,829} The atomic structure of G4 has been solved; the protein crystallized as a dimer that buried the Cys-X-X-Cys active site, which could protect the reactive disulfides from reduction in the cytoplasm.^{35,741} Repression of any one of the three redox proteins results in a block in virion maturation. Thus far, nine viral membrane proteins, all involved in virus entry, have intramolecular disulfides formed by the cytoplasmic redox system (Table 66.2). No evidence that this pathway is involved in the formation of disulfide bonds of other membrane proteins or core proteins has been obtained. Both the entry proteins and the redox system are conserved in all POXVs, suggesting their co-development. The POXV redox system is the only one known to operate on the cytoplasmic side of a membrane.

Occlusion of MVs

The MVs of some chordopoxviruses (e.g., CPXV, ECTV, racoonpox virus, and FWPV) become occluded in a dense protein matrix within the cytoplasm. These have been referred to as A-type inclusions (ATIs) to differentiate them from the sites of virus replication and assembly, which are sometimes called B-type inclusions instead of factories.³⁷⁷ Presumably, ATIs are released following degeneration of infected cells and protect the enclosed MVs from the environment. The major ATI protein of CPXV is a 160-kD myristylated species that may represent up to 4% of the total cell protein at late times after infection.^{258,452,568} Some CPXV mutants form inclusions without virions, implicating a role for an MV-specific protein called 4C,^{690,783} which is encoded by the *A26L* gene of VACV.⁴⁶⁸ The A26 protein has a bridging role between the ATI protein and the A27 protein, which is tethered to MVs through interaction with the A17 protein.³²⁶ Although VACV does not form ATIs, a truncated homologous protein is encoded by some strains^{20,186} and is also associated with the A26 protein.³²⁵ Interestingly, neither the A26 nor the A25 protein is present in EVs.⁷⁸³

Entomopoxvirus virions are also occluded.⁷³ Following ingestion by a larval host, infectious particles may be released in the alkaline pH of the gut. The sequences of homologous occlusion proteins, called spheroidin or spherulin, have been deduced from the ORFs of several entomopoxviruses.^{3,50,297,298,650} These proteins are cysteine rich, have a mass of approximately 100 kD, and lack homology to fusolin, the abundant 50-kD spindle-body protein of entomopoxviruses,¹⁷⁹ the A-type inclusion protein of chordopoxviruses, or the polyhedrin protein of baculoviruses.

FORMATION OF THE EV

Overview

The EV is an extracellular form of POXV that consists essentially of an MV with an additional membrane that is important for virus dissemination.^{92,570} For OPXVs, the extra membrane is frequently formed through an intracellular MV wrapping process followed by exocytosis,^{353,501,571} although direct budding of the MV at the plasma membrane can also

occur.^{316,472,776} In contrast, FWPV exits the cell predominantly by budding.⁹¹ There have been several reviews on various aspects of this process.^{714,813,814}

Wrapping

Some MVs are wrapped by a pair of additional membranes (Figs. 66.12 and 66.13) derived from virus-modified *trans*-Golgi or endosomal cisternae^{313,659,765} that are important for intracellular movement and EV formation. Nine viral proteins have been associated with either the wrapping or EV membrane: A33,⁶³⁴ A34,²²⁷ A36,⁵⁶⁰ A56 hemagglutinin,⁶⁸⁹ K2,⁷⁷⁹ B5,^{235,358} E2,^{219,222} F12,⁸⁸⁰ and F13³¹⁷ (Table 66.5). Of these, A36 and F12 are associated exclusively with the outermost membrane and are not retained in the EV. With the exception of E2, F12, K2, and F13, the proteins have a transmembrane anchor. Association of F13 with the wrapping membrane requires palmitoylation of two cysteines.^{285,313} F12 has been reported to associate with E2²¹⁹ and A36.³⁶⁸ Complex interactions between the A33, A34, and B5 proteins determine the composition of the EV membrane.^{97,230,576,578} A33 has unique C-type lectin domains that could interact with other viral or cell proteins.^{406,742}

Deletion of any of the genes encoding wrapped virion (WV) or EV membrane proteins, except A56 and the associated K2 protein, results in a small plaque phenotype. A56 and K2 deletion mutants have a syncytial phenotype that may be explained by the abrogation of the role of A56 in binding to the EFC.⁸⁰⁵ Studies with mutant VACVs indicate that several proteins are required for efficient wrapping and that severe effects are caused by repression or deletion of the A27 MV protein,^{627,815} the F13 protein,⁸³ and the B5 glycoprotein.^{236,845} The F13 protein is required for Golgi membrane localization of B5³⁴⁷ and has a putative phospholipase motif that is essential for its role in wrapping⁶³³ and induction of post-Golgi vesicles.³⁴⁶ The role of E2 is less defined.^{219,222}

Intracellular Movement and Exocytosis

It has been estimated that it would take a particle as large as a POXV about 5 to 6 hours to move 10 μ M by diffusion,⁷¹⁷ suggesting the importance of an active, directed process. The movement of MVs to the wrapping sites depends on microtubules, but the viral attachment protein is not known. There is some disagreement as to whether the A27 MV protein is required for movement as well as for wrapping *per se*.^{646,815} Long-range intracellular movement of WVs occurs on microtubules^{267,321,618,818,819} rather than by actin polymerization as originally proposed.¹⁶⁴ The A36 and the F12 proteins appear to have roles in microtubular movement. The A36 protein interacts with the cargo binding domain of the light chain of kinesin, a microtubule motor protein.^{366,817} The F12 protein has a structural similarity to the light chain of kinesin and has a motor-binding motif important for virion export.^{309,502}

When the WVs arrive near the periphery of the cell, their migration through the dense cortical actin is facilitated by the action of the F11 protein in preventing RhoA signaling.^{27,161} The outer of the two wrapping membranes fuses with the plasma membrane to liberate the EV with one more membrane than an MV (Fig. 66.13). The externalization of VACV resembles vesicle exocytosis, but the detailed mechanism has not been determined. A role of the ESCRT machinery has been suggested.³²⁴

Only a minority of the externalized virus is found in the medium, whereas most adhere to the cell surface. The ratio of

adherent to released virions varies in different VACV strains,⁵⁶⁹ and in one case was due to a single amino acid difference in the putative lectin binding domain of the A34 membrane protein.⁸⁵ Mutations in the *A33R* and *B5R* genes also enhance release³⁸² and the host Abl-family tyrosine kinases and host phosphoinositide 5-phosphatase SHIP2 are involved.^{470,608} On cell monolayers the adherent EVs can mediate efficient cell-to-cell spread due to actin tails discussed later, whereas the released EVs provide long-range dissemination.⁸⁴

Actin Tail Formation

The efficient cell-to-cell spread of EVs on the cell surface depends on their location at the tip of motile, actin-containing microvilli, which have been visualized by fluorescence and electron microscopy^{164,314,737} (Fig. 66.6). The proteins encoded by the *A33R*, *A34R*, or *A36R* genes are required for the formation of the actin-containing microvilli, and their absence results in a small plaque phenotype.^{632,645,846,849} Nucleation of the actin tails depends on tyrosine phosphorylation of the A36 protein of OPXVs and functional homologs of other POXVs by Src or Abl family kinases.^{220,256,608,609} The phosphorylated A36 protein interacts with the adaptor protein Nck, which results in the recruitment of the Ena/VASP family member N-WASP to the site of actin assembly.^{256,657}

VIRUS–HOST INTERACTIONS

Tropism and Host Range

POXVs frequently have a narrow host range that supports their survival in the wild, although they may occasionally infect and cause disease in other species. Indeed, the eradication of smallpox could not have succeeded if there were a wild animal reservoir. Occasionally, infection of an unnatural host (e.g., the European rabbit by MYXV)²⁵⁰ results in a high mortality. Tropism and pathogenicity are frequently based on the genus- and species-specific properties of defense genes rather than the essential ones conserved in all or most POXVs. This is reflected in the broader species specificity for cultured cells than whole animals. Where restriction occurs, it is usually at a postentry step.⁴⁶⁵ An interesting example of tropism is the ability to infect primary mouse fibroblasts and mice by MYXV only if the IFN response is abrogated.⁸⁰⁹ Under certain nonpermissive conditions of orthopoxvirus infection, viral macromolecular synthesis may be inhibited. Examples are the abortive VACV infection of *Drosophila* cells restricted at the stage of viral DNA replication⁶⁹ and Chinese hamster ovary cells restricted at the stage of intermediate protein synthesis, which can be overcome by the CPXV gene encoding a 77-kD protein.^{330,333,599,726} In addition, VACV K1L deletion mutants are blocked at the stage of early protein synthesis in rabbit RK13 cells^{274,580,600,744} and VACV double K1L and C7L mutants exhibit a similar defect in human cells. Some of the host range effects may be mediated in part by IFN effectors such as protein kinase R (PKR).^{473,837} Host range genes have also been identified in other POXV genera.^{55,435,474}

Effects on the Cytoskeleton

Infection of tissue culture cells with VACV and other orthopoxviruses results in profound morphologic changes consisting of rounding, cell–cell dissociation, and migration that are dependent on viral early gene expression and long-branched

projections that are dependent on late gene expression.³² These cytopathic effects involve alterations in microtubules, actin, and intermediate filaments.^{82,252,488,586,658} The VACV-induced cell motility requires F11 protein-mediated inhibition of RhoA signaling.^{499,789}

Effects on Host Macromolecular Synthesis

The rapid and profound reduction in cell protein synthesis following VACV infection can be seen by labeling cells with radioactive amino acids at various times after infection and analyzing the labeled proteins by gel electrophoresis.^{241,514} Several factors may contribute to the switch from host to viral protein synthesis, and the relative contribution of each factor may depend on the virus multiplicity, cell type, and time of analysis. Inhibition of host protein synthesis frequently remains incomplete until after DNA replication, suggesting a major role of a viral intermediate or late protein. The primary factor in the shutoff of host protein synthesis is a profound reduction in cellular mRNA. After several hours, most of the mRNA present in the cytoplasm of infected cells is viral^{88,158,865} due to accelerated degradation of host species^{67,617,668} coupled with active virus transcription and inhibition of host RNA synthesis and transport.^{67,573,594,668,839} The accelerated degradation of host and viral mRNAs is initiated by the expression of the viral decapping enzymes D9 and D10^{563,564,565,695,724,725} and presumably completed by host cell exonuclease activity.

VACV also hijacks cellular translation initiation factors to expression sites within cytoplasmic factories (Fig. 66.10) and thereby contributing to the suppression of cell protein synthesis.³⁷⁹ The abundance of the cellular translational repressor 4E binding protein decreases during VACV infection, enhancing translation of viral mRNAs.⁸⁰⁷ At high virus multiplicities inhibition of host protein synthesis can occur in the absence of viral gene expression, implicating a virion protein.^{462,506,581} Other studies suggested that small poly(A)-containing RNA molecules are involved.^{33,34,119}

VACV also inhibits nuclear DNA replication.³⁷² This effect may be indirect, although a role for VACV-encoded deoxyribonucleases was suggested.²¹²

Interactions With the Ubiquitin-Proteasome System

Ubiquitination is a posttranslational modification that regulates cellular processes by several mechanisms including protein degradation. Studies with inhibitors suggested that orthopoxviruses require the ubiquitin proteasome system for uncoating cores and DNA replication.^{653,760} A few POXVs encode ubiquitin-like genes, but many more encode modulators of the ubiquitin-proteasome system, including E3 ubiquitin ligases,^{291,340,449,536} ankyrin/F-box-like proteins,^{367,477,720,721,727} and BTB-kelch proteins^{44,63,257,395,826,838} as reviewed.⁵⁹ Some of the ankyrin/F-box-like proteins interact with the skp1 component of the SCF ubiquitin ligase complex to exploit the cell proteasome machinery. Although many of these modulators of ubiquitin are required for virulence, the functions of only a few have been discovered.

Stimulatory Effects on Cell Pathways

To enhance their replication, POXVs may stimulate certain host pathways (e.g., mitogen-activated protein kinase [MAPK] and phosphoinositide 3-kinase [PI3K]/Akt)^{21,716,810} and some,

such as FWPV,¹³⁶ SFV,⁶⁹⁴ Yaba virus,⁵⁴⁴ and MOCV,⁵⁹² induce hyperplasia and tumors. In the case of orthopoxviruses and leporipoxviruses, the hyperplastic effect is due to secretion of a homolog of epidermal growth factor, which binds to ErbB receptors and enhances virulence.^{111,112,134,430,552,738,781} A gene encoding a mitogenic polypeptide with homology to mammalian vascular endothelial growth factor is present in the ORFV genome and may account for the extensive vascularization of lesions and virulence.^{656,841}

VIRAL DEFENSE MOLECULES

Overview

The first line of host defense against viruses consists of nonspecific, innate mechanisms involving IFNs and other cytokines, signaling pathways, complement activation, and natural killer cells; subsequently, specific cytotoxic T cells and antibodies become important. However, POXVs encode multiple proteins that help evade innate and adaptive immune responses. Some inhibitory proteins are secreted from infected cells and resemble host cytokines or soluble immune regulators (virokines)⁴⁰⁰ or cellular receptors that have lost their transmembrane anchor sequences and sequester ligands (viroceptors),⁷⁸⁵ while others interfere with intracellular signaling or effector pathways. In contrast to the highly conserved mechanisms of entry, gene expression, and genome replication that are employed by all POXVs, there is considerable diversity in POXV defense genes, which are adapted to specific hosts. Many of these genes were acquired from their hosts and retain recognizable motifs despite extensive modification, whereas others may represent acquisition of new functions by proteins. Several review articles have been published recently^{36,493,577,585,821} and updates can be anticipated in this fast-moving field.

Extracellular Defense Proteins

Complement Regulatory Protein

VACV and other orthopoxviruses encode a secreted complement control protein (VCP), consisting largely of tandem, inexact copies of a 60-amino acid short consensus repeat found in cellular complement regulatory proteins, that inhibits the classical and alternative pathways of complement activation by binding and inactivating C4B and C3B and accelerating the decay of C3 convertases.^{4,399,400,469,524,641} Although VCP is secreted, some of it is retained on the surface of infected cells by binding to heparin-like molecules²⁶¹ and to the VACV A56 protein.^{200,275,804} Both the VACV and ECTV complement control proteins contribute to virulence.^{276,357} Interestingly, the VARV ortholog of VCP is more potent than the VACV version in inhibiting human complement,^{431,432,639} and strain variation in the MPXV ortholog may contribute to differences in virulence.^{425,433} Although the VACV B5 EV membrane protein also has short consensus repeats, there is no evidence that it has complement inhibitory activity. Host proteins incorporated into the EV membrane could also inhibit complement activation.⁷⁹³

IFN-Binding Proteins

Type I IFN inhibitors encoded by VACV and other orthopoxviruses are present in the supernatants and on the surface of cells and are important for virulence.^{151,190,746,860} Glycosaminoglycans help retain the IFN-binding proteins (BPs) to the cell

surface.⁴⁹⁸ The VACV B18 and orthologs are immunoglobulin (Ig) family proteins with limited sequence similarity to regions of the IL-1 receptor family but not to the ligand-binding subunits of IFN receptors. Nevertheless, these proteins neutralize IFN- α , - β , and - ω depending to some extent on the animal species. Myxoma virus encodes a protein important for virulence that is related in sequence to VACV B18 but is smaller and membrane bound and apparently cannot bind IFN.⁵⁶

Proteins that bind to type II IFNs are secreted by POXVs of several different genera. The IFN- γ BPs of MYXV and orthopoxviruses are related in sequence to the extracellular domain of the IFN- γ receptor.^{13,519,545,786} Deletion of the MYXV and VACV IFN- γ BP attenuate disease in rabbits.^{518,732,747} Because of the low affinity of the VACV IFN- γ BP for mouse IFN- γ compared to human IFN- γ , this cytokine would have a more profound inhibitory effect on VACV in mouse compared to humans, which may be important for interpreting disease models.⁷⁷³ The type I IFN inhibitor encoded by Yaba monkey tumor virus also inhibits type III IFN.³⁴¹

IL-18 BPs

IL-18 induces IFN- γ and acts in synergy with IL-12 to induce natural killer (NK)-cell activation, T-cell activation, and T-helper cell 1 (Th1) response polarization. MOCV, OPXVs, Yaba monkey tumor virus, and some other POXVs encode secreted proteins that are homologous to the mammalian IL-18 BP and which bind and inactivate IL-18.^{90,476,534,715,855,856} Despite limited sequence identity, similar amino acids of the human and viral residues interact with IL-18.⁴⁰⁵ The MOCV IL-18 BP is secreted as a full-length form that binds cell surface glycosaminoglycans through the C-terminal tail and a furin-cleaved form with only the IL-18 binding domain.⁸⁵⁷ ECTV and VACV IL-18 BP deletion mutants exhibit decreased virulence compared with wild-type virus.^{90,606,745}

Soluble Tumor Necrosis Factor BPs

Tumor necrosis factors (TNFs) bind to their cognate receptors and induce pro-inflammatory responses or death of virus-infected cells. Leporipoxviruses,^{666,710,785,861} OPXVs,^{335,438,604,651} and yatapoxviruses¹¹⁰ encode from one to four soluble TNF receptor homologs with varying binding specificities. The VACV CrmE protein shares structural features with mammalian type 2 TNF receptors,²⁸⁰ whereas the tanapox and Yaba-like virus TNF BPs have sequence similarity with major histocompatibility class (MHC) class I molecules.^{110,597,868} CPXV and ECTV also encode a soluble homolog of CD30, another member of the TNF receptor family, which inhibits interaction of CD30 with its ligand.^{555,652}

Soluble IL-1 β Receptor Homologs

IL-1 β mediates a broad-spectrum response to virus infection by binding to a high-affinity cell receptor and triggering a signal transduction pathway. OPXVs encode homologs of the IL-1 receptor that bind IL-1 β .^{11,12,728} Depending on the route of inoculation, deletion of the gene can reduce or enhance virulence. Frameshift mutations in the VARV homolog preclude synthesis of an active protein.

Chemokine Inhibitors

A principal role of chemokines is to coordinate the activation and migration of leukocytes to sites of virus infection. POXVs

encode chemokine-binding proteins and mimics presumably to interfere with the chemokine response. Secreted proteins that bind to a variety of CC chemokines but lack sequence similarity to chemokine receptors are encoded by OPXVs, leporipoxviruses, and parapoxviruses and prevent activation and chemotaxis of leukocytes.^{14,114,125,279,417,607,669,670,711} The structures of several POXV chemokine BPs have been solved and the binding sites determined.^{29,38,877}

Several POXVs encode homologs of the chemokine receptor CCR8. The Yaba-like disease virus protein is inserted into the plasma membrane, binds human CCL1, and activates signal-regulated kinases.⁵³¹ A recombinant VACV expressing the Yaba-like disease virus CCR8 homolog was attenuated in mice.⁵³⁰

Chemokine homologs have been found in MOCV and FWPV. The MOCV-encoded homolog was predicted to be a chemokine antagonist based on the absence of the conserved N-terminal region⁶⁷⁴ and was found to bind specifically to the CCR8 chemokine receptor and to competitively inhibit the binding of I-309, the natural ligand.⁴⁴⁰ Other reports, based mainly on chemotaxis assays, suggested a broader activity.^{180,198,402}

Other Cytokine-Binding Proteins and Homologs

Some parapoxviruses encode a secreted protein that binds granulocyte-macrophage colony-stimulating factor and IL-2.^{196,197} ORFV encodes an IL-10 homolog with a high degree of identity to animal IL-10 molecules.^{253,254,355} The ORFV IL-10 suppresses macrophage activation and exerts an immunosuppressive effect.⁸⁴⁰ Some chordopoxviruses secrete a semaphorin homolog with pro-inflammatory properties that interacts with plexin C1.^{2,154,265,434}

Secreted NK-cell Inhibitor

NK cells have an important role in combating OPXV infections.^{248,559} CPXV and MPXV encode a secreted class I-like protein that acts as a competitive antagonist of the NKG2D-activating receptor and inhibits NKG2D-dependent killing by NK cells.¹²³

Intracellular Defense Proteins

Inhibitors of Cell Pattern Recognition Receptor Signaling Pathways

Cell pattern recognition receptors (PRRs) can detect a variety of viral components including cytoplasmic DNA, single-stranded RNA with triphosphate ends, double-stranded RNA, and viral proteins. The PRRs include Toll-like receptors (TLRs), RIG-like receptors (RLRs), NOD-like receptors (NLRs), and cytoplasmic DNA sensors (DAI, AIM2, and RNA polymerase III). After ligand binding, the TLRs dimerize and recruit cytosolic TIR domain-containing adapter proteins MyD88, MAL, TRIF, TRAM, and SARM, which then activate signaling complexes containing TRAF and IRAK protein pathways, leading to activation of kinases that result in translocation of transcription factors nuclear factor- κ B (NF- κ B), ATF2/c-Jun, and IFN regulatory factors (IRF) that promote expression of pro-inflammatory cytokine genes and IFN. RNA is sensed by TLR3, 7, and 8; RIG-I; and MDA-5.

TLR2, 3, 4, 8, and 9 have been reported to recognize POXV infections. VACV proteins A46, A52, B14, K7, and N1 and homologs in other POXVs have Bcl-2-like structures

and interfere with the TLR signaling pathway at different levels.^{26,60,93,129,137,138,160,216,278,281,282,305,365,373,447,456,457,547,733} DNA sensing of POXVs may occur through at least two pathways: the AIM2 inflammasome⁶⁰¹ and RNA polymerase III.⁷⁹⁰ The VACV E3 protein interferes with the latter mechanism by binding to double-stranded RNA.

NF- κ B Signal Transduction Pathways

The NF- κ B complex comprises a family of dimeric transcription factors that have a central role in responding to viral infections and mediating an inflammatory response. NF- κ B exists in an inactive complex with I κ B α in the cytoplasm until the latter is phosphorylated by I κ kinase (IKK) complex, polyubiquitinated, and then degraded. POXVs can trigger NF- κ B activation but use a variety of mechanisms to suppress this. Modified VACV Ankara, a highly attenuated strain of VACV used as a safe smallpox vaccine and as a vector for other vaccines, has suffered multiple deletions and lost the ability to prevent NF- κ B activation due to double-stranded RNA triggering of PKR in some cells.^{442,548,692} Restoration of the *N1L* or *M2L* genes prevents induction of NF- κ B by the PKR or extracellular signal-regulated kinase 2 (ERK2) pathway, respectively.^{268,315,442,837}

The VACV B14 protein and the nonhomologous ORFV 024 protein prevent NF- κ B signaling by binding to the IKK complex and preventing phosphorylation of I κ B α .^{68,138,214} The VACV A52 Bcl-2-like protein prevents NF- κ B signaling by preventing signaling by Toll-like receptors TRAF6 and IRAK2.⁴⁴⁷

Many OPXVs, other than VACV, encode ankyrin-repeat proteins that bind directly to NF- κ B and prevent the signaling pathway.^{495,496} The nonhomologous ORFV 121 gene encodes a viral NF- κ B inhibitor that also binds to and inhibits the phosphorylation and nuclear translocation of NF- κ B.²¹⁵ MC160, a second death effector domain (DED)-containing protein encoded by MOCV, inhibits TNF- α -induced NF- κ B activation by association with Hsp90 to increase IKK1 degradation and by interaction with procaspase-8.⁵³⁸ Myxoma virus MO13 protein binds NF- κ B.⁵⁹⁸

Inhibitors of IFN Pathways

POXVs encode proteins that prevent signaling and function of IFN response factors. The VACV dual-specificity H1 phosphatase inhibits phosphorylation of the Stat1 and Stat2 transcription factors and blocks type I and II IFN-mediated immune responses.^{448,532} Myxoma virus inhibits type I IFN by blocking the activity of Janus kinase type 2, which is upstream of Stat.⁸⁰⁸ OPXVs encode a double-stranded RNA-binding protein (e.g., VACV E3) that prevents activation of the IFN response PKR, which inhibits translation initiation.^{133a} Loss of E3L can also lead to PKR-dependent activation of IFN regulatory factor 3 and mitogen-activated protein kinases.^{878,879} E3L deletion mutants show host range restriction and enhanced apoptosis, RNA degradation, and IFN sensitivity.^{64,389} The C-terminal end of E3 contains the double-stranded RNA binding domain and the N-terminal segment contains a Z-DNA binding domain important for virulence.⁴⁰⁹ Some POXVs also encode a nonfunctional homolog of the translation initiation factor eIF-2 α (e.g., VACV K3), which inhibits eIF-2 α phosphorylation by PKR.^{181,182} Deletion of K3L increases the IFN sensitivity of VACV.^{65,415} The E3 and K3 proteins have overlapping roles in blocking IFN action.

Apoptosis Inhibitors

POXVs encode a variety of proteins that inhibit apoptosis by different mechanisms to prevent activation of the extrinsic pathway (e.g., TNF, Fas ligand) or intrinsic pathway mediated by mitochondria. Cytokine response modifier A (crmA), a viral member of the serine protease inhibitor (serpin) superfamily initially described as an inhibitor of IL-1 β converting enzyme caspase 1,⁶⁰² blocks apoptosis activated through Fas and TNF receptors^{217,491,762} and potentially inhibits caspase-8, the apical caspase in these pathways.⁸⁸⁵ CrmA deletion mutants replicate normally in most cell lines without inducing apoptosis but do induce apoptosis in a pig kidney cell line.^{444,603} The effect on virulence caused by deletion of CrmA or related Serine protease inhibitor 2 (SPI 2) has varied in different animal models.^{388,764}

MOCV encodes two FLIP proteins with DEDs.⁶⁷⁴ DEDs are also present in cellular FADD and procaspase-8 and mediate their interaction following the binding of TNF or FasL to their receptors. One of the MOCV DED proteins, MC159, has been shown to bind FADD and protect transfected cells against death effector filament formation and apoptosis induced by Fas and other members of the TNF receptor superfamily.^{74,336,422,526,763,775}

Some POXVs encode Bcl2-like proteins (e.g., VACV F1, myxoma m11, ORFV 125, FPV 039, deerpox virus 022) that prevent cytochrome c release from mitochondria by preventing Bak and Bax activation.^{46-48,124,225,246,407,408,551,591,736,759,820,827,828,875} F1 is also a caspase 9 inhibitor, indicating that it is a multifunctional apoptosis inhibitor.⁸⁷⁵

Several POXV proteins prevent apoptosis by additional mechanisms. GAAP (Golgi antiapoptotic protein) is encoded by CMLV, some strains of VACV, and eukaryotes and can inhibit apoptosis mediated by extrinsic and intrinsic pathways.²⁹⁰ The ECTV p28 protein contains a RING finger motif that is required for virulence in mice,⁶⁸³ acts upstream of caspase-3 to block UV-induced apoptosis,⁹⁸ and has been shown to be an E3 ubiquitin ligase.³⁴⁰ Overexpression of the SFV ring finger protein N1 can also block apoptosis induced by UV light.⁹⁹ MOCV encodes a selenocysteine-containing protein, MC66, that is homologous to cellular glutathione peroxidase and can protect cells against the cytotoxic effects of hydrogen peroxide, which could be produced by inflammatory cells, and UV irradiation.⁶⁹³ A putative glutathione peroxidase is also encoded by FWPV.² The MYXV M-T4 localizes to the ER of infected cells and is required for virulence and to prevent induction of apoptosis in a rabbit CD4+ T-cell line or primary rabbit lymphocytes.^{58,318} The MYXV M-T5 protein has a single ankyrin motif, is related to OPXV host range genes, and is required to prevent apoptosis in a rabbit CD4+ T-cell line.⁵¹⁷ The VACV E3 protein was described earlier as a double-stranded RNA-binding protein that protects against the action of PKR and provides resistance to the action of IFN. E3L deletion mutants induced apoptosis in HeLa cells through failure to inhibit PKR.^{389,420}

Inhibitors of Antigen Presentation

CPXV encodes two proteins that down-regulate MHC class I presentation by distinct mechanisms. CPXV203 retains fully assembled MHC class I by exploiting the KDEL-mediated ER retention pathway, whereas CPXV12 binds to the peptide-loading complex and inhibits peptide loading on MHC class I molecules.^{117,118} The VACV A35 protein inhibits MHC class II antigen presentation by an unknown mechanism.^{610,611}

Additional POXV Defense Proteins

The VACV β -hydroxysteroid dehydrogenase contributes to virulence by inhibiting an effective inflammatory response.⁶⁰⁵ The mechanism of action of many other POXV proteins that are not required for replication in cell culture but reduce virulence in animal models remain to be determined.^{57,224,247,684,722,723}

ADAPTIVE IMMUNE RESPONSE TO POXVIRUSES

Adaptive humoral and cell-mediated immune responses are important in clearing poxvirus infections, and knowledge in this area helps to understand the efficacy of vaccines and the design of new ones. Not surprisingly, given their large size and complexity, there are numerous antigens and consequently protective antibodies are directed toward both the MV and EV forms. As in other areas, most information has been obtained for OPXVs, and this has been the subject of several recent reviews.^{508,521,685,859}

ANTIVIRALS

In view of the large number of viral proteins involved in cytoplasmic replication, there are many potential targets for antivirals and many have been investigated over the years.¹⁸⁷ Two potent antivirals have reached the stage of clinical testing. Cidofovir is an acyclic nucleoside analog that is incorporated into the growing DNA strand and inhibits the 5' to 3' chain extension and 3' to 5' exonuclease activities of VACV DNA polymerase.²² The other antiviral is ST-246, which inhibits the wrapping of MVs and formation of EVs by targeting the F13 protein.³⁷¹

EXPRESSION VECTORS

Several attributes of POXVs have led to their extensive use as expression vectors.⁵⁰⁵ These include relative ease of formation and isolation of recombinant viruses, capacity for large amounts of DNA, relatively high expression, and wide host range. Expression has been achieved either by using poxvirus promoters or by employing bacteriophage RNA polymerases and cognate promoters. Recombinant viruses have been used for the synthesis of proteins *in vivo* or *in vitro* and as vaccine candidates to prevent infectious disease and treat cancer.⁴⁶¹ In particular, there has been a recent emphasis on attenuated strains of VACV such as modified VACV Ankara (MVA)⁷⁴³ and NYVAC^{757a} and the combination with DNA priming.¹⁶

are *Orthopoxvirus*, *Parapoxvirus*, *Yatapoxvirus*, and *Molluscipoxvirus*. The majority of human pathogenic poxvirus infections are zoonoses; only variola virus and molluscum contagiosum virus are sole human pathogens. The appearance and general structure of poxvirus virions is depicted in Figure 67.1.

ORTHOPOXVIRUSES

History

The orthopoxviruses are perhaps best known for their most notorious member, variola virus, the causative agent of human smallpox. Smallpox was a febrile rash illness with a variable mortality rate extending to 30% to 40% in some outbreaks. The disease was understood to be a sole human pathogen; extensive experimental studies infecting closely related species failed to produce a viral infection that could be sustained in other host species. Recognition that an infectious agent that caused lesions on the skin and mucosal surfaces on cows and their caretakers could be used to prevent smallpox infection was published by Jenner in 1798.⁹⁴ The viruses cowpox, and later, vaccinia were used in the 19th and 20th centuries to prevent smallpox infection and led to the term “vaccination.” Previously, material derived from convalescent smallpox patients, usually scab material, was used either as an intranasal or percutaneous preparation (termed inoculation) to prevent smallpox in humans.⁵⁹ Ultimately, this, in part, led to our early understanding of the genus *Orthopoxvirus*, where at least cowpox virus was used to cross-protect against smallpox.¹⁰ In addition, the unsuccessful use of infectious material from “spurious” lesions¹²⁸ for smallpox vaccinations, which were later recognized to be of parapoxvirus origin (termed paravaccinia or pseudocowpox), led to the recognition of this distinct group of poxviruses. Vaccinia virus, however, is the most comprehensively studied of the orthopoxviruses.

The history of smallpox and its eradication program has been chronicled in detail,⁵⁹ and is available from the World Health Organization (WHO) website. Perhaps the earliest, most reliable accounts of smallpox are from China in the fourth century AD: contained in writings that distinguish the disease from measles, report that smallpox was endemic in the region, and report the disease was introduced from the west in 48 AD.⁵⁹ Early practices from the 10th to the 18th centuries to control disease included intranasal insufflation with powdered smallpox scabs, quarantine, and cutaneous inoculation with pulverized smallpox scabs. With the recognition that vaccination with cowpox or vaccinia would diminish iatrogenic cases, improvements in disease control were seen. By 1953, smallpox had been eliminated from Europe. The development of freeze-dried vaccine preparations permitted vaccination in

The family *Poxviridae* is extensive, with member species infecting insects (*Entomopoxvirinae*) and vertebrates (*Chordopoxvirinae*). This chapter focuses on vertebrate poxviruses (Table 67.1). Genera of poxviruses with species described to cause human illness

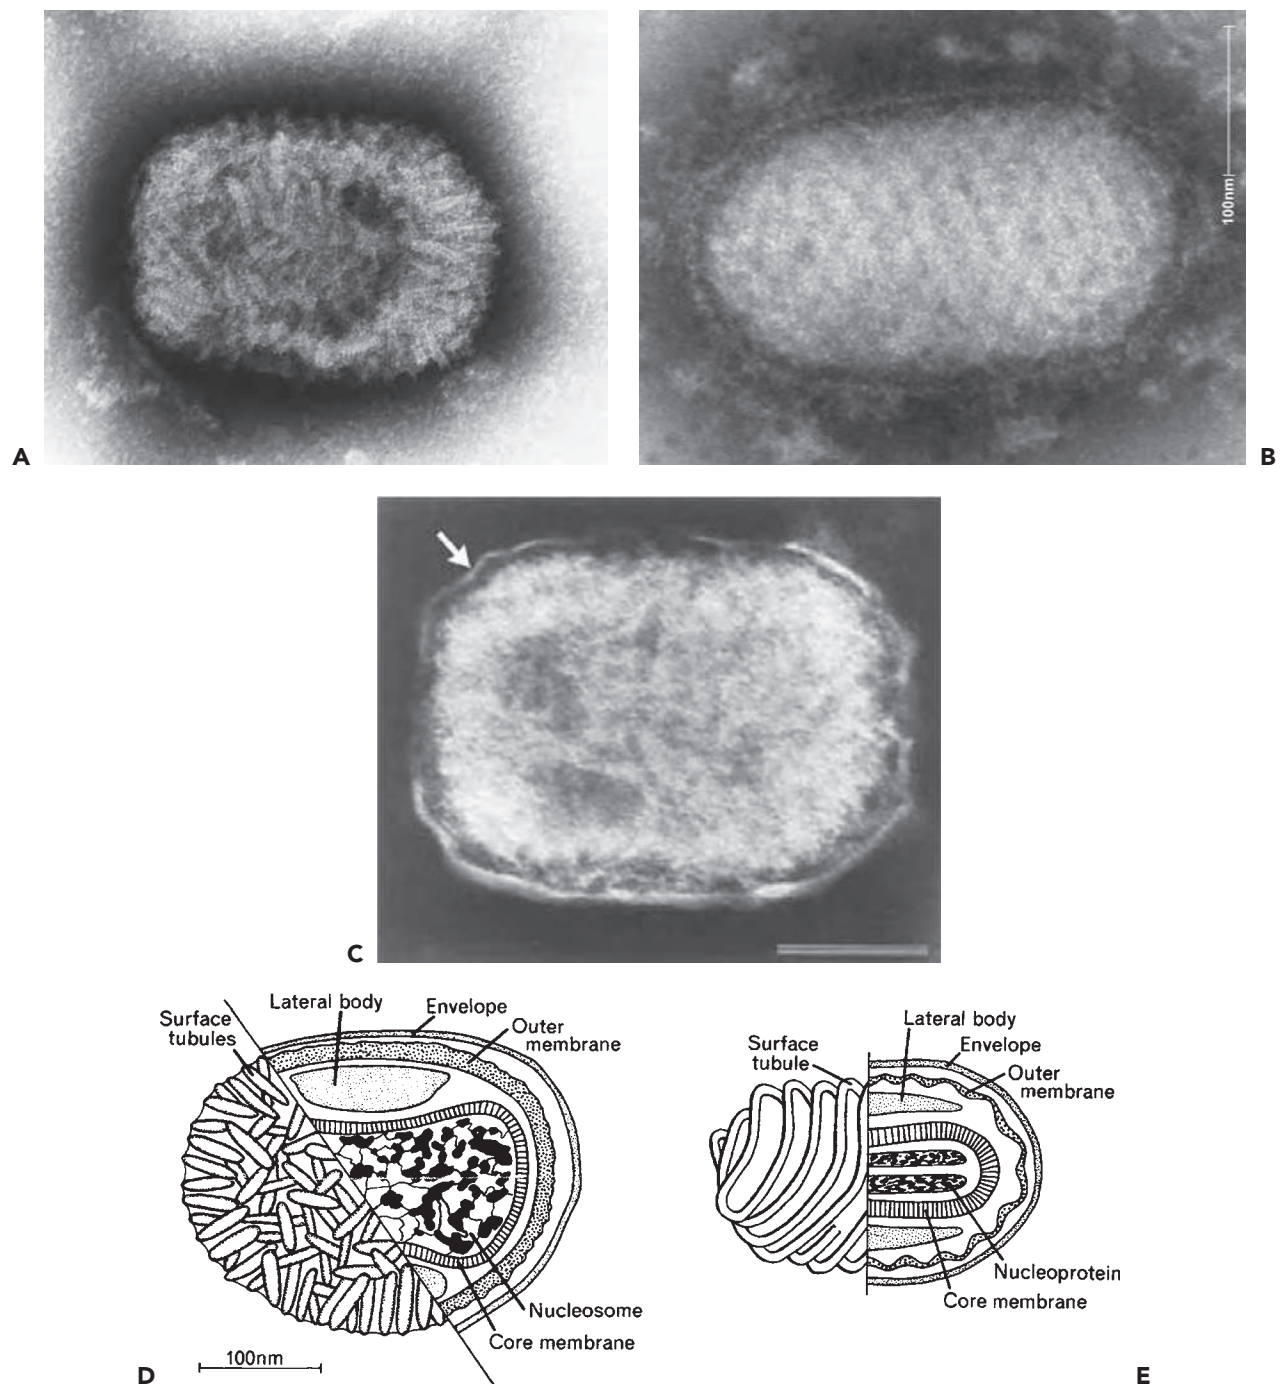

FIGURE 67.1. Negative stain electron microscopic appearance of orthopoxviruses (A), parapoxviruses (B), and yatapoxviruses (C). Bars indicate 100 nm. The structure of the yatapoxvirus and molluscipoxvirus virions is similar to that of the orthopoxvirus virion. As seen in **C**, clinical material from the yatapoxvirus tanapox often contains virion forms with enveloped virions (extracellular enveloped virions [EEVs]; see *arrow*). Knobby, brick-shaped virion forms, consistent with mature virions (MVs), are more often seen in clinical material from orthopoxvirus infections. Parapoxviruses (**B**) are ovoid and smaller, with a distinctive criss-cross filament pattern derived from the wrapping of a surface tubule. **D**: Schematic drawing of a brick-shaped virion typical of an orthopoxvirus. Viral genome DNA and several proteins within the core are organized as a nucleosome. The core has a 9-nm-thick membrane with a regular subunit structure. By negative stain techniques, the virion core assumes a dumbbell shape with large lateral bodies occupying the concavities. The core and lateral bodies are enclosed within a lipoprotein structure, the outer membrane, which is 12-nm thick. The outer membrane surface appears to consist of irregularly shaped tubules that produce the knobby or mulberrylike M form seen in **A**. The majority of infectious virions remain cell associated; others acquire an additional envelope composed of host cellular membrane and virus-specific proteins. These associate on the cell surface to spread to neighboring cells or are released as EEVs to allow more distant spread. **E**: Schematic drawing of parapoxvirus virion showing wrapping pattern of the outer protein tubule, which appears to wrap around the virus. areas outside the cold chain. Largely through the global efforts in design and implementation of WHO-sponsored vaccination programs, the disease smallpox was declared eradicated in 1980 by the WHO. The last naturally occurring cases of smallpox occurred in the Indian subcontinent in 1975 and in the Horn of Africa in 1977. Remaining stocks of variola virus were subsequently moved to two designated WHO Collaborating Centers for Smallpox and Other Poxvirus Infections with maximum containment laboratory facilities. The dismantling of population-based vaccination programs began in 1980. The eradication of smallpox and the discontinuation of vaccination programs likely contribute to the increase in observations of other human orthopoxvirus infections since 1980. In addition, it has enhanced the concerns that if unknown stocks of variola virus exist and were to be used, that the effects on our current population would be profound.

Infectious Agent

By electron microscopy, the orthopoxviruses are large brick-shaped particles; as with all other poxviruses, the virus replicates and matures within the cytoplasm of the host cell. The viral steps involved in entry, fusion, morphogenesis, and release of virus are described in Chapter 66, as well as in a number of detailed reviews.^{145,172} By light microscopy, cytopathic effects in monkey kidney cell lines are apparent and profound. Cell rounding and detachment from neighbor cells is followed by formation of elongated cellular lamellipodia¹⁸⁰; ultimately, cells detach from the substrate. Similar to other poxvirus genomes, the nuclear material is a covalently closed double-stranded genome. Genome length ranges from 170 to 240 kilobase (kb) pairs and its composition is 34% G+C. The central 90 kbp of the central region is highly conserved and contains virion structural genes and enzymes responsible for its DNA replication and messenger RNA (mRNA) transcription; the terminal regions are varied across species and encode genes involved in the host–pathogen interaction. In addition to nucleic acid–based techniques, classification of orthopoxviral species has also been accomplished based on various biological properties (Table 67.2). These include the presence (or absence) of acidophilic-type inclusion (ATI) bodies, and cytoplasmic structures con-

taining collections of virions, and seen in cowpox, ectromelia, raccoonpox, volepox, and skunkpox infections. However, as additional sequence information becomes available, classification of viruses is becoming more complex. For instance, phylogenetic analysis of strains within species was initially supportive for at least two clades of cowpox virus.⁷⁰ A recent analysis, using additional cowpox virus genomic information is supportive of up to five genetic groupings of cowpox virus, and suggests that these groupings may be significant to the species taxa level.³⁰ Current information is supportive of two clades of monkeypox virus^{39,127} and two or three clades of variola virus.^{55,124} The majority of the orthopoxviruses appear to have a broad host range, although the spectrum of disease may vary, depending on what host is infected. This is exemplified by cowpox, which causes discrete localized lesions on the udders of cows but appears to cause a systemic disease in cats. The exception is variola virus, which as we understand the virus, was a sole pathogen of humans and humans appeared to be the sole host. A review on the cellular host range of poxviruses is available.¹³⁹

Pathogenesis and Pathology

Orthopoxvirus infections can be classified as systemic or localized (at the site of virus entry) illnesses. Generalized disease usually manifests with rash. The type of infection that results is dependent on the species of orthopoxvirus, the route of entry, and the genus/species of susceptible animal and its immune status. For this chapter, infections of humans and models to understand infections of normal host humans are largely described. In some cases, understanding of the natural pathogenesis is limited due to the lack of data on the disease pathogenesis in its natural host. The most obvious example is variola. Although clinical descriptions of disease are well notated from early medical writings, the specifics of human pathogenesis are largely derived from inferences evaluating other (e.g., ectromelia, which causes mousepox infection in mice, rabbitpox in rabbits, and monkeypox in nonhuman primates) orthopoxvirus virus species infections of various animal models.^{28,36,65,103} Other respiratory challenge animal models of orthopoxvirus disease are the intranasal vaccinia and intranasal or aerosol cowpox virus challenges of mice.^{79,135} These appear to primarily

TABLE 67.2 Biologic Properties of Orthopoxviruses that can Infect Humans

Property	Variola	Monkeypox	Vaccinia	Cowpox
Host range	Narrow	Broad	Broad	Broad
Pocks of the chorioallantoic membrane (CAM)	Small, opaque, white	Small, opaque, hemorrhagic	Strains vary; large, opaque, white or hemorrhagic	Large, hemorrhagic
Ceiling growth temperature on CAM (°C)	37.5–38.5	39	41	40
Rabbit skin lesion	Small transient, nontransmissible	Indurated, hemorrhagic	Strains vary; indurated nodule, sometimes hemorrhagic	Large, indurated hemorrhagic
Lethality for:				
Mice	Low	High	High to very high	Variable
Chick embryo	Low	Medium	Very high	High
A-type inclusion bodies	No	No	No	Yes
B-type inclusion bodies	Yes	Yes	Yes	Yes
Genome DNA size (kbp)	186	191	192	220

cause upper and lower respiratory infection; virus antigen predominates in the sinuses, intranasal passages, trachea, airways, and lungs. Some evidence of viremic spread is suggested by occasional lesions in the skin or bone marrow.

Nonetheless, the use of animal models of systemic or localized disease, in combination, will be useful in determining efficacy of various therapeutic and/or prophylactic disease mitigation and prevention strategies. Intranasal or aerosol challenge models have been developed using many of the orthopoxviruses in different animal species to represent a respiratory route of infection. Different routes of exposure result in different pathogenesises, involve some different sets of viral proteins, and provide information relevant to understanding disease acquired via contact versus respiratory routes of transmission.¹⁹⁹ Contact transmission has been classically modeled in the footpad model of infection of mouse species with ectromelia,⁵⁶ and more recently, in the dermal ear model with vaccinia, which also provides a model for understanding the immune response to multiple puncture immunization in eliciting (vaccination) protection against smallpox. Models of specific disease manifestations in various immunocompromised hosts have also been developed in order to evaluate the effect of various host factors in both disease pathogenesis and response to, containment of, and clearance of pathogen.

Systemic Disease Pathogenesis

Entry

The cellular receptor used by poxviruses for entry into their host cells is unknown. Member viruses have a broad tropism for entry into tissue culture cells; usually it is the later steps that inhibit completion of the viral maturation process to produce infectious progeny and affect “host range.”^{139,156} A summary of *in vitro* research on *in vitro* (orthopoxvirus) viral entry and fusion mechanisms is available.¹⁴⁵ The portal of entry for orthopoxvirus infection is usually considered to be percutaneous (via contact) or the respiratory tract. Oral routes of exposure have also been reported if very large doses of ectromelia virus are administered¹⁵⁸ to mice; this has been proposed to be a potential route of exposure for cats to cowpox, and squirrels to monkeypox.⁶¹ However, investigations associated around a laboratory-associated outbreak in a mouse colony have suggested that the natural route of transmission is through abrasions in the skin after exposure to infected animals or contaminated fomites.²⁰³ The route of infection also affects the disease course. Inoculation of variola, when unsuccessful as a form of disease prevention, caused iatrogenic disease, with a compressed time from infection to illness with respect to that seen with respiratory acquired disease. Transmission of human smallpox is thought to occur via an upper respiratory route of infection, which is consistent with the typical time frame of disease; infection via contact with contaminated fomites has also been observed. The exposure route/portal of entry for human monkeypox infection may be either percutaneous or upper respiratory; the clinical disease course varies with route of infection.¹⁶⁸ To model a respiratory route of exposure, a variety of aerosol challenges with various orthopoxviruses have been used to infect various animal species; these may produce initial stages of disease that occur in lower portions of the respiratory tract than seen in natural human infection. An alternative exposure route has been intranasal challenges.^{65,73,90,135,170,207} For one North American orthopoxvirus, volepox, mechanical arthropod vec-

tors have been suggested as a route of transmission to California voles¹⁶⁷; this has not been observed in other orthopoxviruses, although it is a route of transmission, and portal of entry, for fowlpox and *Capripoxvirus* and *Leporipoxvirus* species. Importantly, in rabbitpox virus challenge studies, natural respiratory/airborne transmission appeared to occur over 12 feet.²⁰⁷

Site of Primary Replication

When the skin is the portal of entry, studies with ectromelia have suggested the virus needs to be introduced to the dermis if systemic infection is to eventually result.¹⁷¹ Virus replicates in the Malpighian layer of the epidermis, and dermal infection consisted of fibroblasts and histiocytes; the latter were likely responsible for subsequent movement of virus to the lymphatics to initiate the course of events required for systemic illness.

When the respiratory tract has been used as portal of entry, in experimental aerosol infections, likely dependent on particle size, a combination of upper and lower respiratory tract infections has occurred. Viral replication occurred in alveolar macrophages and small bronchioles, and then moved to regional pulmonary lymph nodes. Epidemiologic understanding of the natural human infections with variola virus to cause smallpox suggests that the common method of transmission was via a respiratory route. Primary infection is believed to have occurred within the mucosal surfaces of the nasopharyngeal tract, and then move to the regional lymphatics by extrapolation from that seen with ectromelia and rabbitpox virus studies. A recent review of aerosolized rabbitpox virus infection in rabbits is available.²⁰²

Virus Spread

Our understanding of orthopoxvirus spread after initial infection and spread to regional lymphatics comes again from studies of ectromelia in mice, rabbitpox in rabbits, and monkeypox in nonhuman primates. The use of fluorescent-antibody stains of fixed tissues and titers of infectious virus in organs at various time points in disease has provided the majority of this information. More recently, bioimaging studies have also been applied.¹³² Virus moves from the regional lymphatics to the bloodstream to cause a primary viremia, and then multiplies in the spleen, liver, bone marrow, and other reticuloendothelial organs. After this, a second viremic period ensues, followed by seeding of distant sites, specifically the skin, and generation of the characteristic generalized rash. Virus particles are mostly cell associated during viremic phases of disease. In ectromelia, the virus replication in the macrophages of the liver spreads to the parenchymal cells of the liver causing necrosis; similar pronounced replication and effect of virus is found in spleen and bone marrow. In certain inbred mouse species, the disease is so pronounced at this stage that mortality ensues prior to development of rash.²⁸

Experimental challenge studies of monkeypox infection, which clinically resembles smallpox more than mousepox, have been done in several species of animals, including nonhuman primates, and have demonstrated infectivity and pathogenesis through a number of routes of infection, including aerosol, intranasal, or parenteral administrations. Recent reviews of this literature are available.^{36,89} The pathological changes associated with aerosol challenge of cynomolgus monkeys have been described.²¹³ The time course of disease, and related mortality,

is related to the virus challenge dose.¹⁴⁷ Initially, there is regional lymph node uptake and replication of virus in lymphoid organs, followed by viremia. An eruption begins, with lesions forming macules, papules, vesicles, pustules, and crusts to scar formation from days 6 to 23 of infection. Areas of inflammation and cell necrosis have been seen in tonsils, lymph nodes, digestive tract, testes, ovaries, kidneys, liver, and lungs. Epithelial degeneration, necrosis, and intracytoplasmic bodies have been seen in skin and mucous membranes.

Use of high doses of variola in nonhuman primate challenges, via parenteral route of administration, produced a severe illness with hemorrhagic manifestations of disease.⁹³ Apoptosis and a dysregulated cytokine response are believed to be responsible for what has previously been referred to as the “toxemia” of smallpox.

Pathology

Cytoplasmic inclusion bodies are a typical histopathological feature of orthopoxvirus infections. Two morphologies (Fig. 67.2) are manifest: A-type inclusion bodies, where virions are clustered within an intracytoplasmic structure (Fig. 67.2D), or B-type inclusions (Guarnieri bodies), which are perinuclear and contain the viroplasm and maturing viral particles. Not all orthopoxviruses form A-type inclusions; a longer predicted form of the A-type protein (130 to 160 kD vs. 90 kD) appears to be required. In cowpox, the A-type inclusion is termed a Downie body; in ectromelia, it is termed a Marchal body. The North American orthopoxviruses also form A-type inclusions.

In humans, it is the rash that has been extensively studied during smallpox disease pathogenesis. The viral lesion primarily develops in the epidermis, although early changes of capillary dilation, endothelial cell swelling, and perivascular cuffing with lymphocytes, macrophages, plasma cells, and eosinophils are seen in the papillary layer of the dermis prior to development of the rash lesion. Subsequently, within the epidermis, the cells of the Malpighian layer swell and vacuolate to undergo ballooning degeneration. B-type inclusions could be seen in the cytoplasm. The cytoplasm continues to enlarge, loss of nuclear material is noted, and coalescence of vacuoles via cell rupture creates reticulating degeneration of the middle and upper layers of the stratum spinosum. In the next stages, the vesicle is formed. Cells of the lower stratum spinosum and basal layer exhibit nuclear condensation and nuclei fragment. The cavity of the vesicle (later the pustule) thus develops adjacent to the dermis, permitting the “deep-seated” feel of the smallpox pustular lesions. The cavity retains some cellular remnants that create a multiloculated appearance, also adding to the firmness of the lesion. When polymorphonuclear cells move into the cavity, pustulation occurs. High titers of virus are found within the lesions.²³ In mucosal surfaces, the absence of a horny layer allowed the necrosis caused by proliferation of virus within the epithelium to create ulcers and led to liberation of large quantities of virus into the oropharynx.¹⁸³

Evaluation of other organs in human smallpox has been done in select autopsies from cases where death was attributed to ordinary or hemorrhagic forms of smallpox.²³ Some of the observations from autopsies of ordinary smallpox case deaths have been that, unlike ectromelia, liver and spleen do not show as extensive evidence of viral replication and necrosis that is seen in ectromelia infection of susceptible mice. In general, mild pathological changes are seen in the lungs. This is in contrast to

FIGURE 67.2. the more severe lung pathology seen in apparent cowpox infection of captive felines, which caused death and was associated with severe bronchopneumonia.¹³⁴ Similarly pulmonary disease has been seen in respiratory rabbitpox infection of rabbits, where in addition to subpleural nodules focal areas of consolidation were noted.⁶⁸

The pathology of the localized lesions of cowpox in humans has been studied. The lesions are characterized by a marked inflammatory and erythematous response.¹² The bulk of the lesion is caused by hypertrophy and proliferation of the basal cell layer of the epidermis, together with massive inflammatory

infiltration. Infection usually spreads into follicles, and typical A-type inclusions are usually seen.

Immune Response: Primary Infection

Early responses to virus infection are the production of interferons, nitric oxide, and elicitation of natural killer (NK) and macrophage cellular functions prior to the development of adaptive, antigen-directed B-cell and T-cell responses. Both complement pathways are also activated by the host in response to virus infection. Studies of ectromelia virus infection in various mice deficient in one or more immune response pathways demonstrate the importance of interferon γ (IFN- γ), granzymes A and B, perforin, and CD4 and CD8 T cells in the clearance of primary infection. Antibody is also essential.^{37,38,155} Additional studies in other orthopoxviruses demonstrate successful clearance of a primary orthopoxvirus infection to be dependent on the adequate production of IFN- γ and Th1 cytokines¹⁶³ to promote an effective cytotoxic T-lymphocyte (CTL) effector response. Experiments where high levels of interleukin 4 (IL-4) are produced early in infection, expressed from recombinant challenge poxvirus, show delayed or inhibited ability of the host to clear the recombinant poxvirus.^{6,92,190} In secondary infection, as in the circumstance of infection post vaccination with a heterologous orthopoxvirus, antibody alone may be sufficient.¹⁵⁴ This latter finding has also been demonstrated in vaccine provided protection for monkeypox infection.⁵⁴

Macrophages and NK cells are involved in early responses to infection and are used for clearance of orthopoxvirus infections.^{57,102} The secreted IFNs are needed for containment of primary orthopoxvirus infections.^{132,175} The cellular secretion of tumor necrosis factor is another host response to orthopoxvirus infection. Viral infection can induce apoptosis, and the poxviruses have a number of strategies to inhibit apoptosis, which are also involved in host range, that have been reviewed²⁰⁵ and are described in Chapter 66.

Studies designed to better define the pathogenesis of adverse effects of current replicative vaccinia used as smallpox vaccine in individuals with atopic dermatitis (AD) provide additional information about the early steps in viral pathogenesis and the normal and aberrant host innate immune responses, as well as factors important in containment of viral infection to produce localized disease. In AD, there is an abundant Th2 response.¹⁵ Human skin explant models have been developed to understand eczema vaccinatum, the dissemination of vaccinia virus in individuals with atopic dermatitis.⁸⁴ In human atopic dermatitis skin, an abundance of Th2 cytokines IL-4 and IL-13 (with respect to normal skin) diminish the effectiveness of an innate immune response to vaccinia virus, in a signal transducer and activator of transcription (STAT)-6-dependent manner, allowing increased replication of virus. In normal skin, viral replication is inhibited by cathelicidins. In human keratinocytes infected by vaccinia, the cathelicidin LL-37 is downregulated through the effects of IL-4 and IL-13.⁸⁵

As mentioned previously with regard to apoptosis, the orthopoxviruses express a number of proteins that have been shown *in vitro* or *in vivo* to evade or modulate the host's response to orthopoxvirus infection. There are a number of reviews that summarize this work,^{3,62,99,186,210} and the specific effects of these proteins may have different manifestations, depending on the route of challenge or the model of infection used.^{2,199} One strategy that the orthopoxviruses have evolved is soluble secreted

proteins to bind the host cytokines, complement C3b and C4b, chemokines, interferons, and their receptors. These include viral proteins that bind tumor necrosis factor (TNF), IL-1 β , and IFN- γ via secretion of an ortholog of the mammalian protein that lacks its intermembranous and signaling portions. The orthopoxviral proteins that bind the type I interferons, as well as those that bind IL-18 (which regulates IFN- γ) and the chemokines, have apparently evolved to develop a structure distinct from the mammalian receptors for these immune response proteins; the IL-18 binding proteins are similar to the mammalian IL-18 regulatory binding proteins.

The orthopoxviruses have strategies to inhibit intracellular antiviral effects of the IFNs. All orthopoxviruses sequenced to date have a homolog of the vaccinia E3L protein, and most have a homolog of the K3L protein. E3L homologs bind double-stranded RNA (dsRNA) and have at least two functions: one is to inactivate the IFN-induced dsRNA-dependent protein kinase (PKR), and the other is to inactivate 2'5'-oligoadenylate synthetase. K3L mimics eIF-2 α , which prevents eIF-2 α phosphorylation and inhibits autophosphorylation (activation) of PKR. E3L inhibition of PKR also interferes with its proapoptotic functions^{13,109,122} to affect cellular host range of vaccinia virus. A number of orthopoxvirus proteins have also been identified that interfere in various intracellular steps of the IL-1R and toll like receptor (TLR) signaling pathways, ultimately regulating the nuclear factor kappa B (NF- κ B) pathway¹⁴⁴ and IFN regulatory factors (IRFs). Two vaccinia proteins appear to act early in the pathway and target multiple nonoverlapping TLR pathways; A52R and A46R both block NF- κ B activation. A vaccinia virus with A52R deleted appears attenuated *in vivo*. A46R inhibits TIR domain containing adapter-inducing interferon β (TRIF)-dependent signaling to inhibit IRF3 activation and TRIF-dependent gene induction.¹⁹² TRIF may have an additional role in inhibition of vaccinia replication in the macrophage.⁸² The product of the vaccinia A52 open-reading frame (ORF) has the ability to block NF- κ B activation via a number of pathways. Additional vaccinia proteins (K1L and N1L) block specific steps further downstream in the signaling pathway for NF- κ B activation.^{51,191}

The orthopoxviruses also express proteins that interfere with various steps in apoptosis.¹⁶⁰ The vaccinia F1L protein interferes with mitochondrial components of the apoptotic cascade²⁰⁴ through interaction with Bak. The serpin, SPI-2 (vaccinia) or crmA (cowpox), inhibits caspase 1 and 8; the latter effect protects target cells against CTL lysis induced by the Fas pathway.

The host-pathogen relationship of orthopoxviruses is complex and involves many host and viral factors. Host responses to pathogenic and nonpathogenic orthopoxvirus infections examined using microarray techniques^{25,72} provide additional information regarding complex host-pathogen interactions. In variola parenterally infected nonhuman primates, which models aspects of the second viremia and subsequent disease course in severe forms of smallpox,⁹³ peripheral blood mononuclear cell transcripts showed an increase in interferon-associated gene transcripts not evident in animals that rapidly succumbed to infection.¹⁷⁹ There was also a significant upregulation of Ig gene transcripts. Overall, there were minimal TNF- α and NF- κ B responses.

Immune Response: Vaccination

The protective effects of smallpox vaccination and correlates of protection remain an area of active investigation.⁶² Vaccinia

strains provided an effective strategy for use as a live viral vaccine to prevent smallpox and to facilitate disease eradication. Smallpox disease was eradicated 25 years ago, at a time when the current advances in immunology were not available to dissect the mechanisms of protection. Although some studies demonstrated high levels of neutralizing antibody after vaccination or smallpox infection were protective,¹⁸¹ other studies have demonstrated the level of CD8+ T-cell memory correlates with protection from subsequent viral disease.²⁰⁸ A number of studies have demonstrated long-lived Ig and T-cell responses to smallpox vaccination^{77,78}; individuals vaccinated in childhood demonstrate long-lived B-cell memory response, and a longer duration of CD4 T-cell memory than CD8 T-cell memory,^{4,5,42,50} which may be important for long-term B-cell memory.

However previous remote childhood smallpox vaccination was not completely protective against acquisition of the related disease monkeypox when it was introduced in the United States in 2003.¹⁰¹ Studies with ectromelia virus infection in mice demonstrate the requirement of a virus-neutralizing antibody response, even in the absence of CD8+ T cells, in order to control a pathogenic virus challenge after immunization.

Release from Host

For smallpox, data on virus shedding show infectious virus in the oropharyngeal secretions, with lesser amounts in the urine and conjunctivae.¹⁸² Levels of virus in oropharyngeal secretions were highest just after rash onset between 3 to 4 days post fever onset, the clinical manifestation of the secondary viremia; however, virus could be detected up to 2 weeks post fever onset in cases with more pronounced rash (confluent disease). Virus could be detected in urine over approximately the same time period during illness. In localized orthopoxvirus infections, such as vaccination with vaccinia virus (smallpox vaccination), virus can be found at the lesion until the scab separates.¹¹⁴

Epidemiology

Of the orthopoxviruses that infect humans, only variola is not a zoonotic infection. Interhuman transmission of variola virus occurred through the inhalation of large airborne respiratory droplets, containing infectious variola virus, from infected persons. Transmission usually required prolonged face-to-face or other close contact, although airborne transmission over longer distances had been reported.⁵⁹ Transmission via fomites or contact with the infectious material from the rash also occurred. Aggregate data, collected during the smallpox eradication campaign, suggest a secondary attack rate of 58.4% in unvaccinated close or household contacts, and a secondary attack rate of 3.8% in previously vaccinated close or household contacts.⁵⁹ Case fatality rates for variola major varied with the type of disease manifest, but aggregate rates of 10% to 30% in various outbreaks have been recorded. Severity of disease correlated with rash burden and was also more severe in children and pregnant women. Variola alastrim minor is a variant of variola with a case fatality rate of <1%, but manifest with apparent similar epidemiologic features of human-to-human transmission.

Monkeypox has a more complex epidemiology; two genetically discrete virus clades have been described,^{39,127} with apparent distinct clinical and epidemiologic parameters. Identification of human infections, in Western and Central Africa, was first made in 1970. Investigations in the Congo Basin country Zaire, now the Democratic Republic of Congo (DRC),

demonstrated that human-to-human transmission of monkeypox was less than that of smallpox. The secondary attack rate in unvaccinated contacts of monkeypox cases were calculated to be 9.3% versus 37% to 88% for smallpox.⁹⁶ Prior smallpox vaccination (3- to 19 years previously) appeared to be 85% protective at preventing disease acquisition in contacts and also ameliorated disease severity. Overall, although the majority of cases identified acquired disease from a presumed animal exposure(s), only 28% of cases were ascribed to person-to-person transmission. A case fatality rate of ~10% was observed in unvaccinated persons; the majority of fatalities and severest disease manifestations was observed in children younger than the age of 5. Serosurveys suggested subclinical infection may have occurred in up to 28% of close contacts of monkeypox patients in some communities, which may have contributed to the rarity of sustained generations of human-to-human transmission in household and other close contact situations.

Because the majority of cases were believed to have acquired disease through animal exposures, case-control studies were attempted to determine the source of infection. These were not definitive because the population appeared to have multiple daily contacts with the same animals in settlements, forests, or cleared agricultural areas. Among primary cases, recent close contact via hunting, skinning, killing, cooking, or playing with carcasses was identified to *Cercopithecus*, *Colobus*, and *Cercocebus* primate, *Cricetomys* terrestrial rodent, and *Funisciurus* and *Heliosciurus* squirrel species. Ecologic studies, usually using convenience samples of animals collected in areas surrounding human cases in West and Central Africa, demonstrated orthopoxvirus and sometimes monkeypox-specific seroprevalence in various members of these species, but these were not reported for *Cricetomys* species. This work has been comprehensively reviewed.⁹⁶ Virus was only found in one euthanized, moribund squirrel species *Funisciurus anerythrus*. The prevailing hypothesis was that squirrel species were the likely reservoir of disease. Near the end of the 1980s, disease surveillance waned after modeling studies based on the epidemiologic observations of secondary attack rates from human-to-human exposure suggested that limited number of transmission events were feasible, even with low population immunity provided by waning immunization rates in the populations of Central Africa. The virus had not, therefore, adapted to survive solely through human infection and would not manifest with the same human-to-human transmission dynamics of smallpox. This work also led to the recommendations to not continue routine smallpox vaccination in individuals considered at risk for monkeypox infection.

A re-emergence of disease was noted in 1996 in the DRC; a salient observation from a series of investigations was that more cases were derived from secondary human-to-human contact (88%) than seen in 1981 to 1986 investigations (28%). This was, in part, attributed to a larger population of humans fully susceptible to disease because of the cessation of routine smallpox vaccination in 1980 after smallpox eradication. Another observation was that disease epidemiology showed more cases in the older child/young adult population.⁸⁸ Disease mortality (1%) was observed to be lower than previously seen in 1981 to 1986. This may have been due to a smaller demographic of very young children (ages 0–4 years) being infected, may have been due to technical limitations on the investigations, or may have been due to the inclusion of chickenpox cases in

the case definition. Whereas previous ecologic serosurveys of animal populations had implicated tree squirrels as having significant orthopoxvirus seroreactivity, these investigations were the first to show orthopoxvirus seroprevalence in terrestrial rodents (*Cricetomys emini*) and in one domestic pig (*Sus scrofa*) sampled. Outbreaks of monkeypox, some with apparent high interhuman transmissibility,¹²⁰ and ongoing surveillance documents an increased incidence of monkeypox in regions of the Congo Basin.¹⁶⁹

Monkeypox virus was introduced to the United States in 2003 via a consignment of wild-captured animals from the West African country of Ghana. The virus was identified as belonging to a distinct clade of monkeypox, which included previous West African monkeypox isolates and isolates derived from earlier outbreaks in primate colonies. Detailed comparison of the clinical and epidemiologic characteristics of the U.S. cases (imported from West Africa) with DRC cases from 1981 to 1986 demonstrated significant differences in human disease manifestation¹²⁷; pronounced rash and more severe illness were seen in the Congo Basin cases. Controlling for age and vaccination status, disease severity remained more extreme in the Congo Basin than in the U.S. case patients. Monkeypox-related mortality and human-to-human transmission were only seen in the Congo Basin. These data are suggestive of at least two populations of monkeypox viruses being maintained in Africa.

Cowpox

Cowpox is a virus found in Europe and Asia that is maintained in rodents; in Britain, these are bank voles and woodmice (Table 67.1).^{16,31,35} Human infection is a zoonosis. The domestic cat is one common source of human infection,¹⁷ and this probably explains the occurrence of cases in children; 26% of 54 cases identified between 1969 and 1993 were in children younger than 12 years.¹² Most feline and human cases occur between July and October, with only occasional cases between January and June. Human cases occur in which no source is traced, but despite detailed investigations, only three human cases in Britain since 1968 have been traced to a bovine source, and no case of bovine cowpox has been detected since 1976.

Cowpox virus has a wide host range, and an interesting finding has been the occurrence of cowpox in a variety of captive exotic species in European zoos. Susceptible animals have included cheetahs, lions, anteaters, rhinoceros, elephants, and okapi, and infection has occasionally been transmitted to animal handlers.^{11,158,159} Recent outbreaks of human infections with cowpox virus in Europe have been traced to rat populations used in the pet trade.²⁹

Vaccinia

The origin of vaccinia is unknown, and no natural host for the virus is known. However, a number of vaccinia variants have been described. Buffalopox has been described in India; human infection results from contact with infected animals. It is not known whether buffaloes are a reservoir or whether other wildlife is involved, as with cowpox. Similarly, there have been increasing reports of vaccinia viruses infecting cattle handlers in Brazil. Cantagalo virus has been classified as a vaccinia variant, but other similar nonidentical vaccinia-like viruses have also been reported in the region.^{44,47,48,123,197} Studies have begun to investigate the disease ecology of these viruses.¹

Clinical Features

Variola: Smallpox

Naturally acquired variola virus infection caused a systemic febrile rash illness; the course of clinical features is schematically diagrammed in Figure 67.3. For ordinary smallpox, the most common clinical presentation, after an asymptomatic incubation period of 10 to 14 days (range 7 to 17 days), was fever, which quickly rose to about 103°F, sometimes with dermal petechiae. Associated constitutional symptoms included backache, headache, vomiting, and prostration. Within a day or two after incubation, a systemic rash appeared that was characteristically centrifugally distributed (i.e., lesions were present in greater numbers on the oral mucosa, face, and extremities than on the trunk). Lesions commonly manifested on the palms and soles. The rash lesions were initially macular and then advanced to the papular stage, enlarging and progressing to a vesicle by day 4 to 5 and a pustule by day 7; lesions were encrusted and

FIGURE 67.3. The clinical development of discrete ordinary smallpox. After respiratory droplet exposure and infection, an asymptomatic incubation period of 7 to 17 days precedes prodromal symptoms of high fever and malaise. Subsequently, rash develops 2 to 4 days after the prodrome. The fever diminishes at the onset of rash development. The characteristics of smallpox and chickenpox rash are contrasted.

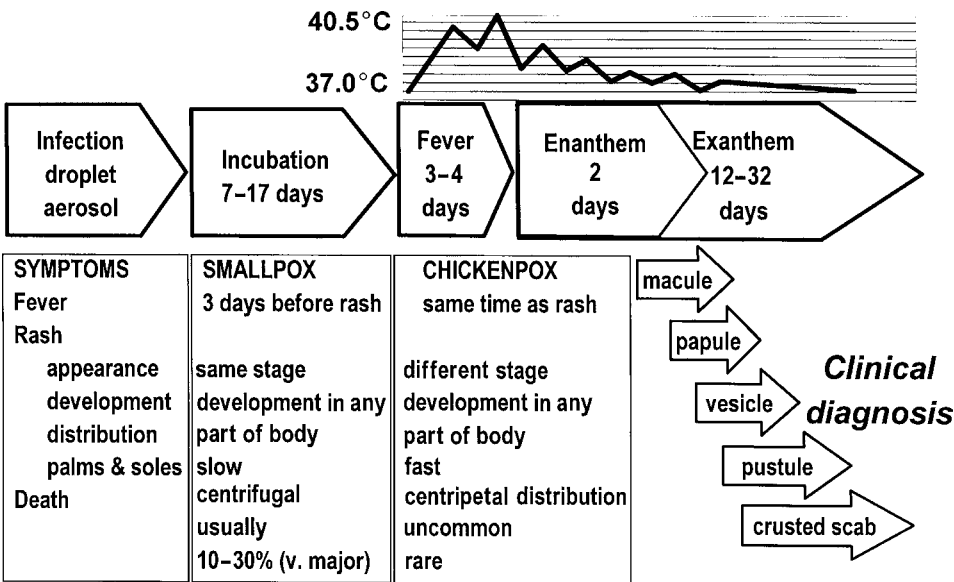

FIGURE 67.4. The rash of smallpox. The smallpox recognition card used during the Intensified Smallpox Eradication Programme of the World Health Organization, showing the nature and distribution of the rash of ordinary smallpox. (From Fenner F, Henderson DA, Arita I, et al. *Smallpox and its Eradication*. World Health Organization, Geneva, 1988, with permission.)

scabby by day 14 and then sloughed off. Skin lesions were deep seated and in the same stage of development in any one area of the body. Images of the classic presentation of ordinary smallpox are depicted in Figure 67.4. Milder and more severe forms of the rash were also documented. Less severe manifestations (modified smallpox or *variola sine eruptione*) occurred in some vaccinated individuals, whereas hemorrhagic or flatpox types of smallpox are believed to have developed as a result of an impaired immune response of patients.

Variola major smallpox was differentiated into four main clinical types: (a) ordinary smallpox (~90% of cases) produced viremia, fever, prostration, and rash; mortality rates were generally proportionate with the extent of rash and ranged, using the WHO classification, from less than 10% for ordinary discrete to 50% to 75% for the rarer ordinary confluent presentation; (b) (vaccine) modified smallpox (5% of cases) produced a mild prodrome with few skin lesions in previously vaccinated people and had a mortality rate of less than 10%; (c) flat smallpox (5% of cases) produced slowly developing focal lesions with generalized infection and had an approximate fatality rate of 80%; and (d) hemorrhagic smallpox (<1% of cases) induced bleeding into the skin and the mucous membranes and was invariably fatal within a week of onset. Notably, prior vaccination did not appear to protect from mortality associated with

the more severe flat or hemorrhagic forms of disease. A discrete type of the ordinary form, with typical febrile prodrome and rash, resulted from *alastrim variola minor* infection.⁵⁹

The WHO established a system for classifying smallpox case types on the basis of disease presentation and rash burden. The hemorrhagic and flat types have been briefly described previously. The ordinary type was subgrouped into three categories, which were based on the extent of rash on the face and the body: confluent, semiconfluent, and discrete. In ordinary confluent disease, no area of skin was visible between vesiculopustular rash lesions on the trunk or the face. In ordinary semiconfluent and discrete disease, patches of normal skin were visible between rash lesions on the trunk and face, respectively. Disease modified by vaccine presented with sparse numbers of lesions. Survival from infection conferred lifelong immunity.

Monkeypox

In humans, clinical disease is believed to result from either respiratory, percutaneous, or permucosal exposures. Classical descriptions from the active surveillance program in Zaire, now the DRC, have historically provided most of our understanding of human monkeypox. Following an incubation period of 7 to 17 days (mean 12 days) a prodrome of fever, headache, backache, and fatigue begins. The cutaneous eruption evolves

FIGURE 67.5. Human monkeypox. The day 8 appearance of monkeypox rash on a 7-year-old girl from the Democratic Republic of Congo. Prominent lymphadenopathy is apparent at the angle of the chin and in the inguinal areas. (From Breman JG, Kalisa R, Steniowski MV, et al. Human monkeypox 1970–1979. *Bull WHO* 1980;58:165–182.)

similar to that of smallpox. Lesions evolve in the same stage in any one part of the body from macules, papules, vesicles, pustules, and then crust and scar. This is apparently more common in unvaccinated individuals⁹⁶; in previously vaccinated individuals, pleomorphic presentation of rash lesions was observed. Following resolution of the rash, hypopigmentation is followed by hyperpigmentation of the scarred lesions. Pronounced lymphadenopathy clinically distinguishes monkeypox from smallpox. Lymphadenopathy in the facial area: cervical, postauricular, submandibular, and inguinal can be quite pronounced. Images of the typical presentation of human monkeypox in the DRC are in Figure 67.5.

Vaccinia Virus

Multiple-puncture vaccinia virus infection, using a bifurcated needle, is currently used in the smallpox vaccination regimen used for laboratory workers using orthopoxviruses¹⁷⁷ and public health care personnel and military in the United States. Most commonly, the infection progresses through a standard course of events from vesicle to pustule (Fig. 67.6). However, of all vaccines used today, the smallpox vaccine, comprising live replicative vaccinia virus, has one of the highest rates of adverse events.⁴¹ Major complications include progressive vaccinia, eczema vaccinatum, generalized vaccinia, postvaccinial encephalitis, accidental infection, and carditis (Fig. 67.7).

Progressive vaccinia, previously called vaccinia necrosum or vaccinia gangrenosum, is a rare and often fatal vaccine complication in persons with severe deficiencies of cellular immunity.²⁴ In 1968 in the United States, there were five cases among 6 million primary vaccinees and six cases among 8.6 million revaccinated persons¹¹⁶; 4 of these 11 patients died. Progressive vaccinia is characterized by progressive, often painless growth and spread of the vaccine virus beyond the inoculation site, often leading to necrosis, sometimes with metastases to other body sites.⁶⁴ The possibility of progressive vaccinia should be considered if the vaccination site lesion continues to progress and expand without apparent healing more than 15 days after vaccination.¹⁵⁰ Initially, limited or no inflammation is present at the inoculation site and histopathological examination shows an absence of inflammatory cells.¹⁰⁴

Eczema vaccinatum (EV) can occur in people with a history of atopic dermatitis (eczema), irrespective of disease severity or activity. This complication is the clinical result of local spread or dissemination from the primary vaccination site in such persons or the result of the skin of an individual with atopic dermatitis contacting the unscabbed vaccination site of another person.^{64,149} A localized or generalized papular, vesicular, or pustular rash anywhere on the body or localized to previous eczematous lesions is the clinical presentation of eczema vaccinatum. Systemic illness with fever, malaise, and lymphadenopathy may occur. In the national U.S. surveillance of smallpox vaccination that was done in 1968, there were 66 cases (no deaths) of eczema vaccinatum among 14.5 million vaccinees (4.6 cases per million) and 60 cases (one death)

FIGURE 67.7. Severe complications of vaccination. **A:** Eczema vaccinatum in the unvaccinated contact of a vaccinated sibling. **B:** Progressive vaccinia, previously known as vaccinia necrosum, in a child with a congenital defect in cell-mediated immunity. **C:** Generalized vaccinia 10 days after vaccination. **D:** Ocular vaccinia. (From Fenner F, Henderson DA, Arita I, et al. *Smallpox and its Eradication*. World Health Organization, Geneva, 1988, with permission.)

among their several million contacts.¹¹⁶ In one study, early vaccinia immune globulin (VIG) administration reduced mortality from 30% to 40% to 7%.¹⁰⁶

Generalized vaccinia is a nonspecific term that is used to describe a vesicular rash that develops after vaccination. Excluding dissemination associated with eczema vaccinatum and progressive vaccinia, it has been extremely rare to document virus in these lesions.¹⁰⁵ True generalized vaccinia is believed to represent the end product of viremic spread of virus, and no predisposing factors have been identified. Generalized vaccinia was estimated to occur in about 242 of every 1 million primary vaccinations¹¹⁶; likely many of the historic reports also included allergic and inflammatory responses to the vaccine.²⁰⁰

Postvaccination encephalomyelitis (PVEM) is a rare but serious complication that usually occurs in primary vaccinees. The frequency of its occurrence differed widely from country to country and with the strain of vaccinia virus used in the vaccine. The incidence of PVEM was lower with the New York City Board of Health (NYCBOH) vaccinia virus strain (the U.S. vaccine strain) than with the strain used in other countries.⁵⁹ No

predisposing factors for PVEM are known, although host factors are believed to be important; the pathophysiology of PVEM is not well understood. Patients have variably displayed clinical and diagnostic features suggestive of a postimmunization demyelinating encephalomyelitis or direct viral invasion of the nervous system. This postvaccination reaction typically occurs 11 to 15 days following vaccination. Symptoms of PVEM include fever, headache, vomiting, confusion, delirium, disorientation, restlessness, drowsiness or lethargy, seizures, and coma. The cerebrospinal fluid can demonstrate elevated pressure, but generally has a normal cell count and chemistry profile.¹⁹³ Infants younger than 2 years old can also develop a rare, postvaccination encephalopathy (PVE) similar to PVEM. Acute onset of PVE occurs earlier in the postvaccination period (6–10 days after vaccination), presents with the same symptoms as PVEM, and may also include hemiplegia and aphasia. Diagnosis of PVE or PVEM is one of exclusion because there are no specific diagnostic tests to confirm the diagnosis of this complication and there are many other infectious and toxic etiologies that can result in similar clinical symptoms. Accidental infection occurs when virus from the vaccination site is transferred to another site or to another person via intimate skin contact. This usually occurs in primary vaccinees rather than revaccinees. Accidental self-inoculation, which most commonly occurs on the face, mouth, lips, or genitalia, is usually not serious and requires no specific treatment. Inoculation of the eye or eyelid is more serious and can be sight threatening if not evaluated and treated appropriately. In the 5 years between 1963 and 1968, ocular vaccinia was observed in 348 persons; 259 were vaccinees, and 66 were contacts of vaccinees. Of these, 22 had evidence of corneal involvement and 11 experienced permanent defects.^{116,178}

Cardiac adverse events had not been reported before 2003 in any person vaccinated with the NYCBOH strain. Myocarditis and pericarditis were documented in 18 of 230,734 primary vaccinees immunized with the NYCBOH strain in 2002 and 2003.⁷⁶ Arrhythmias and myocardial ischemia have also been described recently, but the association with vaccination is not as clear.

Vaccinia viruses in the Indian subcontinent (buffalopox) and in Brazil (Cantagalo virus and related strains Aracatuba virus, Belo Horizonte virus, Passatempo virus, and others) have been described to cause human infection in handlers of buffalo or cattle.⁴⁸ Up to 10 lesions have been described on the hands or arms of the human handlers; fever, lymphadenopathy, backache, and fatigue have also been associated symptoms. Transmission is believed to occur via unprotected contact with active lesions present on animal teats and udders. Interhuman transmission of buffalopox to family members has been reported to occur via contact.¹¹³

Cowpox

Cowpox also causes localized lesions in humans (Fig. 67.8D), and lesions in cows are typically found on their teats and udders (Fig. 67.8A). Most information is available from a detailed analysis of 54 human cases investigated during 1969 to 1993.¹² Lesions are generally restricted to the hands and face, and most patients (72%) have only one lesion. Multiple lesions may be caused by multiple primary inoculations, autoinoculation, and rarely by lymphatic or viremic spread. Occasionally, a very severe infection, and death, may occur usually in immunosuppressed individuals.

FIGURE 67.8. Cowpox, pseudocowpox, and orf virus infections of animals (A–C) and the lesions caused by these viruses on the digits of humans (D–F). A: Cowpox ulcer on teat of cow, 7 days after onset of symptoms. B: Pseudocowpox (milker's nodule) virus infection of cow teat. C: Orf virus scabby mouth in a lamb. D: Cowpox. E: Milker's nodule. F: Orf. (A and B courtesy of E. P. J. Gibbs; C courtesy of A. J. Robinson; D courtesy of A. D. McNae; E and F courtesy of J. Nagington.)

The lesion passes through macular, papular, vesicular, and pustular stages before forming a hard black crust. The lesion is usually quite painful, and erythema and edema are common at the late vesicular and pustular stages (Fig. 67.8A). There is usually lymphadenitis, fever, and general malaise, often referred to as “flulike.” These features are usually severe in children, and absence from school or work is common; 16 of 54 patients (30%) were hospitalized. Most cases take 6 to 8 weeks to recover; in some cases, it may take up to 12 weeks. Scarring is usually permanent.

Diagnosis

Differentiating Smallpox from Other Diseases and Conditions

Prior to its eradication, smallpox as a clinical entity was relatively easy to recognize, but other exanthematous illnesses were mistaken for this disease. For example, the rash of severe chickenpox, caused by varicella-zoster virus, was often misdiagnosed as that of smallpox. However, chickenpox produces a centripetally distributed rash and rarely appears on the palms and soles. In addition, in the case of chickenpox, prodromal fever and systemic manifestations are mild, if they manifest at all; the lesions are superficial in nature; and lesions in different developmental stages may present in the same area of the body. Other diseases and conditions that could be confused

with vesicular-stage smallpox include monkeypox, generalized vaccinia, disseminated herpes zoster, disseminated herpes simplex virus infection, drug reactions (eruptions), erythema multiforme, enteroviral infections, scabies, insect bites, impetigo, and molluscum contagiosum. Diseases confused with hemorrhagic smallpox included acute leukemia, meningococcemia, and idiopathic thrombocytopenic purpura. The Centers for Disease Control and Prevention (CDC), in collaboration with numerous professional organizations, has developed an algorithm for evaluating patients for smallpox. The algorithm assists in differential diagnoses of the vesiculopustular stage of rash. The algorithm and additional laboratory testing information are available at www.bt.cdc.gov/agent/smallpox/diagnosis/evalposter.asp and www.bt.cdc.gov/agent/smallpox/diagnosis/rashtestingprotocol.asp. An evaluation of the algorithm has been published.¹⁸⁹

Laboratory

A variety of diagnostic strategies are available for the laboratory diagnosis of orthopoxvirus infections. Negative stain electron microscopy cannot differentiate the virions of orthopoxvirus from those of yatapox or molluscipox, but the clinical and epidemiologic information will likely aid interpretation. Some of the classic methods for distinguishing orthopoxvirus species are depicted in Table 67.2. Protein-based diagnostics can be used to detect the genus, but for the most part cannot identify individual species.⁴⁵ An IgM capture serologic assay may provide a useful tool for assessing orthopoxvirus disease incidence¹⁰⁰ and may provide utility in assessing infectious etiologies of encephalitic symptoms associated with orthopoxviruses.¹⁸⁷

The majority of tests that can differentiate orthopoxvirus species, however, rely on nucleic acid testing. Identification of orthopoxvirus species can be accomplished through morphologic observations of virus pock growth on chorioallantoic membrane of embryonated eggs. A number of nucleic acid test strategies have been developed and published; the majority are polymerase chain reaction (PCR) based.^{115,125,126,153,185}

Prevention and Control

Vaccination has been the historic mechanism for control of interhuman transmissible orthopoxvirus infections. The successful eradication of smallpox, declared in 1980 by the WHO, was largely due to the effective use of vaccinia vaccine strains worldwide in an extensive immunization program. Vaccination could also be used postexposure to provide protection; greatest protection was afforded if provided within days of contact to a patient,^{136,173} and if the contact had previously been vaccinated.⁸⁰ For laboratory workers, vaccination is recommended in some countries¹⁷⁷ for those using any orthopoxvirus capable of causing disease in humans; in others, only for those working with the more human pathogenic orthopoxviruses. Because of the adverse events associated with the use of current vaccinia virus vaccine strains, evaluation of vaccination regimens using attenuated vaccinia strains^{107,138,143} or subunit vaccines have been undertaken.

Recent work has also focused on the development of antiorthopoxvirus therapeutic strategies. Compounds with direct antiviral effects, as well as others that inhibit viral use of cellular functions, have been evaluated and demonstrate efficacy in various animal model systems of orthopoxvirus challenge.^{21,86,108,117,162,165,166} At least two antiviral agents, with different mechanisms of antiviral action, are moving into

advanced stages of research and development for orthopoxvirus treatment. A DNA polymerase inhibitor, cidofovir, and an orally bioavailable derivative CMX-001™ of the parent compound has activity against orthopoxviruses in tissue culture, and in treatment of various orthopoxvirus-animal model challenges. ST-246 (Tecoviramat™), a novel compound that functions to inhibit later stages of viral maturation and egress has been shown effective against orthopoxviruses in similar studies. These products have been used investigationaly, with vaccinia immune globulin, for the treatment of severe vaccinia infections related to vaccination.^{33,34,201}

PARAPOXVIRUS

History

Parapoxvirus infections are widespread, worldwide in sheep, goats, and cattle. Human infections from these sources are a common occupational hazard for those in contact with infected animals or, less commonly, fomites. The current International Committee on Taxonomy of Viruses (ICTV)—recognized members of the genus *Parapoxvirus* are orf virus (ORFV), bovine papular stomatitis virus (BPSV), pseudocowpoxvirus (PCPV), and parapoxvirus of red deer in New Zealand (PVNZ). BPSV and PCPV are maintained in cattle, whereas ORFV is maintained in sheep and goats, but all three are zoonoses. A squirrel parapoxvirus had been described by electron microscopic morphology as a parapoxvirus, but genome sequencing suggests it is an unclassified poxvirus.¹⁹⁴ Distinct parapoxvirus infections of, and viral species from, red deer in New Zealand^{83,173} have been characterized. PVNZ has not been observed to infect humans. In the United States, a novel deer-associated parapoxvirus was characterized as the cause of cutaneous infections in two hunters. The viruses appear related to pseudocowpoxviruses.¹⁷⁶ Other tentative members of the genus are camel contagious ecthyma virus or chamois contagious ecthyma virus, which causes a disease initially called Ausdyk or camel contagious ecthyma in camels; this may also be the virus responsible for cases of “camelpox” described in humans in the Middle East.⁹⁷ Another tentative member is seal parapoxvirus.^{14,198} A poxvirus infection of reindeer¹¹⁰ has been classified as an orf virus and demonstrated the ability of orf to cross species barriers.

Human infection with ORFV is termed orf. Most commonly, the disease is transmitted from sheep or goats. The disease in animals is alternately referred to as orf, contagious pustular dermatitis, contagious ecthyma, or scabby mouth. Disease in sheep was recognized as early as 1787; the earliest known report of human disease was made in 1879. Human infection with PCPV is commonly called milker’s nodule. The disease is transmitted from dairy cattle, and is referred to as paravaccinia or pseudocowpox in these animals. Notably, this disease was not formally distinguished from that caused by the orthopoxvirus cowpox until the end of the nineteenth century, although Jenner did recognize “spurious” forms of cowpox on cow teats, described in the late 1700s as “pustular sores” lacking “bluish or livid tint”.⁹⁴ Human disease with BPSV is termed *bovine papular stomatitis* and is transmitted from beef cattle; the disease name when virus infects cattle is the same. Initial descriptions of disease in beef cattle were published in 1884; transmission of infection, causing illness in humans, was described in 1953.¹⁵² Subsequent reports demonstrated humans could transmit disease

to cattle.³² Human disease with seal parapoxvirus is called sealpox and is transmitted from seals. Human infection of a seal handler was first reported in 1987⁸¹; the virus was first detected in seals and sea lions in 1969.²⁰⁹

Infectious Agent

By negative stain electron microscopy, parapoxviruses appear ovoid with a criss-cross surface appearance (Fig. 67.1), generated by the genus’ characteristic outer spiral tubule structure. The particles of orf virus are 260-nm long by 160-nm wide; pseudocowpox virions appear a bit larger 300 nm by 190 nm. The viruses obtained from clinical materials grow most readily on primary ovine or bovine cell culture systems and do not grow in embryonated eggs. A few strains have been laboratory adapted to grow on VERO cells or MRC-5 cells; this has been associated with genome changes and attenuation of the virus.

The separation of the parapoxviruses into at least four distinct groups has been based on natural host range, pathology, and nucleic acid methods, including restriction endonuclease, DNA/DNA hybridization, and, most recently, partial or full gene or genome sequence analyses.^{49,142,194} As with other poxviruses, the latter studies have shown that the parapoxviruses share extensive homology between central regions of their genomes but much lower levels of relatedness within the genome termini. The high G+C content of parapoxvirus DNA is in contrast to most other poxviruses (except for molluscipoxvirus) and suggests that a significant genetic divergence from other genera of this family has occurred. DNA sequencing of the genome of two parapoxviruses, species BPSV and ORFV, has allowed a detailed comparison with the fully sequenced genomes of other chordopoxviridae. These studies have provided a genetic map of ORFV and BPSV, and revealed that within the central core of the genome, 88 ORF are conserved with the other sequenced chordopoxviridae.⁴⁹ This conservation is not maintained in the genome termini where insertions, deletions, and translocations have occurred. Studies have demonstrated a great degree of diversity within species via comparison of three complete orf genome sequences.¹⁴²

Pathogenesis and Pathology

Most of the work on the pathogenesis of parapoxvirus infections comes from studies of orf and paravaccinia viruses. Most animal models have used orf virus in sheep; however, there is detailed literature on the pathologic appearance of human orf lesions. Infection occurs via cuts and scratches and remains localized. After entry through nonintact epithelium, virus replicates in the regenerating epidermal keratinocytes.¹⁴⁰ Lesions are produced by hypertrophy and proliferation of epidermal cells, often marked, and leukocyte infiltration. Histologic examination shows many small multilocular vesicles within the dermis; true macrovesicles rarely occur.^{98,211} In the first 2 weeks, the epidermis shows ballooning degeneration in the keratinocytes, and the dermis shows newly formed thin-walled blood vessels with an inflammatory infiltrate. As the infection progresses, in weeks 2 to 3, the intraepidermal vesicles described previously are seen in some cases, with intraepidermal bullous lesions in others. At this point, keratotic material could be visualized on the skin surface. Viral particles were only visualized in the epidermis and were present in the greatest numbers in the first 2 weeks after infection.⁹⁸

The immune response in natural human infection has been investigated.²¹¹ There is a vigorous but short-lived cell-mediated

response and a relatively poor and short-lived humeral response. This is consistent with the occurrence of second infections in 8% to 12% of individuals.^{174,211} Studies of the immune response to orf infection in sheep have been reviewed.⁷⁴ Immunohistochemical studies of lesions demonstrate large numbers of neutrophils, lymphocytes (T and B), and dendritic cells surrounding virus-infected epidermal cells.⁵ In comparison of primary versus reinfection lesions, the appearance of CD8+ T cells and B cells are later in primary infection than in reinfection; CD4+ T cells are the predominant cell present in either lesion. Virus replication is decreased in reinfection lesions with respect to that seen in primary lesions. Studies of cytokine response demonstrated γ -IFN mRNA+ cells, and some TNF- α mRNA+ cells in reinfection, but not in primary infection. Cellular depletion studies¹³⁰ have suggested that CD4+ T cells, IFN- γ , some CD8+ T-cell responses, and some humeral components are necessary for host resolution of infection. Passive antibody transfer, however, does not appear to protect young animals from infection,²⁷ nor does there appear to be a predominant neutralizing antibody response to orf infection.⁴³

The parapoxvirus genomes are predicted to express several proteins involved in the host–pathogen interaction; the majority of those studied have been in the context of orf virus. Orf virus expresses a homolog of the mammalian vascular endothelial growth factor (VEGF), which has been demonstrated to be a viral virulence factor. The absence of the orf protein produces an attenuated virus¹⁸⁴; it is hypothesized that the viral protein stimulates keratinocyte growth likely to provide cell substrate for viral replication; in addition, it inhibits apoptosis.¹⁸⁴ The product of a viral gene, OVIFNR, a homolog of vaccinia E3L, prevents inhibition of host protein synthesis to permit virus utilization of the protein synthetic apparatus. The mechanism for this is protein binding to dsRNA formed during viral infection, preventing PKR kinase activation and subsequent eIF-2 phosphorylation. Other virally encoded proteins are postulated to evade or modulate the host immune response. These include proteins that inhibit granulocyte-macrophage colony-stimulating factor (GM-CSF) and mimic IL-10. *In vitro* studies implicate the orf expressed IL-10 homolog in impairment of an effective immunologic memory response, and is a virulence factor.^{63,119} A chemokine binding protein expressed by the virus can interfere with recruitment of dendritic cells to the site of orf infection.¹¹⁸

Epidemiology

Human infections with parapoxviruses are an occupational hazard of farm workers, abattoir workers, veterinary surgeons, and students, and so on. It is most common in the lambing and calving seasons, and more commonly reported in sheep workers than in cattle workers; this probably reflects differences in animal husbandry. Of 191 cases with a known source surveyed from 1978 to 1995, 84% had an ovine source and 16% were from cattle. During the same period, 32 cases occurred in abattoir workers.¹¹

Factors responsible for ongoing transmission have been attributed both to the environmental stability of orf virus in scab material (although infectivity wanes over time) and to the manifestation of chronic infections in some animals.¹²⁹ There is no known latency state for this or any other poxvirus. Transmission of virus to humans and to animals is via direct contact with lesions or with fomites.

Clinical Features

The progressive stages of human infection have been described in detail,^{98,121,211} and illustrations have also been provided⁶⁶ (Fig. 67.8B, C, E, and F). Lesions start as erythematous papules and progress to a “target” stage. This, seen 1 to 2 weeks after infection, has a red center surrounded by a white halo and an outer inflamed halo. The lesions progress to a nodular and then papillomatous stage, which often has a “weeping” surface. In some patients, lesions may enlarge and persist for some weeks before resolving, and may cause some concern. The lesion resolves via a crusting stage, which may last some weeks. Very large granulomatous lesions can occur, usually in immunocompromised individuals.

Most patients have only one lesion, but multiple primary lesions may occur. Systemic reaction is relatively uncommon, and the lesion is often not particularly painful. Lymphadenopathy is present in some patients, and lymphangitis is also observed but is relatively uncommon. *Erythema multiforme* was reported in one-third of patients reported in one case series.⁹⁸ However, because many ordinary uncomplicated cases of orf go unreported, the actual incidence of *E. multiforme* is probably low.

Diagnosis Differential

Differential diagnosis of parapoxvirus lesions can include ecthyma gangrenosum (a pseudomonas infection of immunocompromised persons), cutaneous anthrax, erysipeloid, and tularemia or tumor. Clinical diagnosis of uncomplicated cases in patients with a known animal contact should not cause difficulties but has been confused with anthrax. However, farmworkers and so on recognize the infection and tend not to seek medical attention for routine cases. Consequently, a disproportionately large number of reported cases have no known contact with infected animals. Of approximately 500 cases surveyed from 1978 to 1995, some 45% had no such contact. Clinical diagnosis of such cases, particularly if severe or prolonged, may be difficult. In particular, large weeping granulomatous or papillomatous lesions may be misdiagnosed as malignancies.

Laboratory

With negative stain electron microscopy, virions with the characteristic morphology of parapoxviruses are usually easily seen in lesion extracts, and this provides a rapid, certain diagnosis of the genus. The virus can be grown in cell culture, but this is not attempted routinely in laboratories that do not maintain primary ovine or bovine cultures.

A number of methods derived from limited or complete genomic analysis have been used for nucleic acid detection (PCR) and laboratory diagnosis of infection.^{91,125,196} Species-specific and species-generic protein-based diagnostics for parapoxviruses have also been developed.⁴³

Prevention and Control

Most workers at risk get infected at some stage, and reinfection is not uncommon. Individuals should take care not to spread infection by autoinoculation or to contacts, including animals. The vaccine used to control orf in sheep is fully virulent and has caused human infection. Work is underway to create live attenuated viruses that can be used as vaccines. Treatment options

are limited; anecdotal reports have described the use of topical cidofovir,¹³⁷ or topical imiquimod. Other options may be topical formulations of interferon-modulating compounds such as imiquimod.

MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum virus causes a disease characterized by one or more benign, self-limited skin “tumor(s)” or papular eruption(s), occurs worldwide, and is regarded as a specific human infection.²⁰ There is no evidence of disease transmission between humans and other animals, although lesions resembling molluscum and containing pox virions have been detected in species other than humans (e.g., horses, chimpanzees).

Infectious Agent

Four subtypes of molluscum contagiosum, characterized by restriction endonuclease digests, have been described.¹⁴⁶ Disease presentation by all subtypes appears to be similar. The genome of molluscum contagiosum virus subtype I has been sequenced¹⁸⁸ and encodes a number of novel gene products involved in its pathogenesis and evasion of the immune system, including, among others, an IL-18 binding protein and apoptosis inhibitors. Attempts at propagating the virus in tissue culture have been unsuccessful.

Pathogenesis and Pathology

Molluscum contagiosum does not cause systemic disease and remains localized at the site of inoculation. Molluscum contagiosum lesions have long been known to have a distinctive pathology. Description of the characteristic molluscum bodies, or Henderson-Patterson bodies, was made in 1841 by Henderson and Patterson. A good review of the histopathological features of the infection is available¹⁶¹ (Fig. 67.9A). The onset of infection occurs when virus begins replicating, extending upward, in the lower layers of the epidermis.¹⁵⁷ The asymptomatic incubation period is variable but can be protracted. As the infection progresses, the epidermis hypertrophies and

extends down into the underlying dermal strata. Characteristic inclusions (molluscum bodies) are formed in the prickle cell layer and gradually enlarge as the cells age and migrate to the surface. These cells are replaced by hyperplasia of the basal cell layer; few to no viral structures are seen in the stratum basale. The structure of the basement membrane remains intact; the hypertrophied epidermal cells, with their cytoplasm occupied by a large acidophilic granular mass (i.e., the molluscum body), project above the skin to appear as a tumor. Little to no inflammatory infiltrate is seen until late in disease, just prior to natural resolution of the lesion.

Clinical Features

Molluscum infection occurs as a result of molluscum contagiosum coming in contact with nonintact skin. The characteristic lesion begins as a small papule and, when mature, is a discrete, 2- to 5-mm diameter, smooth, dome-shaped, pearly or flesh-colored nodule, which is often umbilicated (Fig. 67.9B). A cheesy, off-white or yellowish material is easily expressed from lesions. There are usually 1 to 20 lesions, but there may occasionally be hundreds. Because of multiple simultaneous infections or mechanical spread, the lesions may become confluent along the line of a scratch, and satellite lesions are sometimes seen.

In children, molluscum lesions occur mainly on the trunk and proximal extremities, and in adults, they tend to occur on the trunk, pubic area, and thighs; however, in all cases, infection can be transmitted to other parts by autoinoculation. In males infected with human immunodeficiency virus (HIV), molluscum lesions appear to occur along the beard line, and with persons with infections involving the face, there have been reports of ocular involvement. Individual lesions last for about 2 months, but the disease usually lasts 6 to 9 months. More severe and prolonged infection tends to occur in individuals with impaired cell-mediated immunity, including persons with HIV infection.⁶⁶

Diagnosis

The clinical appearance of molluscum lesions in normal cases is generally sufficiently characteristic to permit clinical diagnosis. Brick-shaped virions can usually be seen in large numbers if the cheesy material expressed from the lesion is examined by negative-stain transmission electron microscopy. The virus has not been cultured in standard tissue culture systems. The characteristic histopathology of these lesions is diagnostic, but PCR methods have also been described for use in identifying molluscum contagiosum.^{125,195}

Epidemiology

Molluscum contagiosum virus occurs worldwide, and increasing reports of the disease have paralleled the number of reported cases of AIDS. Traditional modes of transmission are associated with mild skin trauma such as abrasions, direct contact with a lesion, and, in some cases, fomites (e.g., shared towels); however, there is increasing evidence that the disease is sexually transmitted and that genital lesions are more common than lesions elsewhere on the body.²⁰ The disease presents a significant concern for individuals whose children are in day care or school situations, where potential transmission to other children may exist. Secondary spread of lesions may occur by autoinoculation (excoriation of primary lesions and spread to areas of normal skin) and shaving. No known animal reservoir exists.

FIGURE 67.9. Molluscum contagiosum. **A:** Section of a skin lesion visualized by hematoxylin-and-eosin staining. **B:** Lesions of molluscum contagiosum in a human. (Courtesy of D. Lowy.)

Prevention and Control

The covering of lesions and the use of proper hand hygiene after contact with lesions should prevent transmission in most situations.

Molluscum contagiosum infection is benign and recovery is usually spontaneous, but treatment may be sought for cosmetic reasons, particularly for facial or multiple lesions. Various treatments have been tried, including cryotherapy, mechanical curettage, and chemical treatments, such as podophyllin/podofilox, cantharidin, iodine, and tretinoin. Irritation has been a side effect of many of the chemical treatments. Topical application of a 3% Cidofovir antiviral cream or suspension has been reported to be beneficial, as has the use of potentially immune-modulating cimetidine or topical imiquimod therapy.⁴⁰ The absence of well-controlled trials makes it difficult to assess the efficacy of various therapeutic regimens. For individuals with AIDS and molluscum, the use of highly active antiretroviral therapy, with improvement of CD4 cell counts, appears to be efficacious.

YATAPOXVIRUSES

History

Human infection with tanapox virus, a species of the genus *Yatapoxvirus*, was first recognized in the Tana River area of Kenya in 1957 and was best characterized during post-smallpox eradication surveillance efforts. An account of 264 laboratory-confirmed cases from Zaire (now the DRC), with color illustrations, is available,⁹⁵ as is information on the virus itself.¹¹² The genome of the virus has been sequenced. Yaba-like disease of monkeys is caused by the same virus that causes tanapox in humans,⁵³ and it was responsible for outbreaks in three primate centers where animal handlers were infected. There have been a few reports of human disease outside Africa that have been published and illustrate the need to consider poxvirus etiologies of illness in travelers returning from, and emigrants from, areas where the virus is endemic.⁵⁰

Yaba monkey tumor virus (YMTV), the other member of the genus, was recovered from rhesus monkeys in Nigeria.¹⁵¹ Although no naturally occurring human infections have been reported, the virus does cause disease if injected subcutaneously or intradermally in humans or nonhuman primates.⁶⁷

Pathogenesis and Pathology

The pathogenesis of tanapox or Yaba-like disease is incompletely understood. The clinical features, described here, are

suggestive of some systemic phase of disease. The ultimate skin lesion shows epidermal thickening with marked ballooning degeneration; eosinophilic inclusions are often visible. YMTV causes localized histiocytic “tumors” at the site of inoculation. After inoculation into the dermis, an accumulation of proliferating spindle-shaped cells begins about 1 week later. This continues for 4 to 6 weeks, resulting in the formation of a “tumor.” The lesion can become superinfected with bacteria. Virus remains cell associated, and the lesion appears to regress as mononuclear cells move from the periphery into the lesion.¹⁵¹

The genomes of both species encode a novel TNF-binding protein, distinct from the receptor homolog expressed in orthopoxviruses. Studies of the protein expressed from tanapox demonstrate its high affinity for human, not murine or rabbit, TNF.^{26,186} This and other unique immune-modulatory proteins expressed by one or both members of this genus likely affect their pathogenesis.

Epidemiology

Tanapox virus is restricted to Africa, principally to Kenya and the DRC, and is thought to have a simian reservoir.⁵² Cases of direct primate-to-human transmission, via a break in skin, have been described in animal handlers, although such cases appear to be extremely rare.⁷⁵ Several factors have led to speculation that an insect or arthropod intermediary may be involved in transmission of tanapox virus to humans. Persons confirmed to have tanapox infection have denied contact with nonhuman primates but have reported arthropod and culicine mosquito bites prior to infection; in patients who developed multiple lesions, there was no evidence that the virus had been spread mechanically.⁹⁵ Furthermore, the seasonal variation of human tanapox infections follows the activity of local arthropod populations. No human-to-human transmission has been reported.

Clinical Features

Tanapox infection begins with a short febrile (38°C to 39°C) illness of 2 to 4 days that is sometimes accompanied by headache, backache, or prostration. The eruption of a lesion is often heralded by pruritus at the site of the outbreak. The lesion appears as a hyperpigmented macule, often with central elevation, and the macule then evolves to a papule, with palpable induration. Fever and systemic symptoms wane as the lesion manifests. The papule then becomes more “pocklike” but contains no fluid; umbilication or the formation of a pseudocrust has been reported at this stage. Typically, the papule evolves into a firm, deep-seated, elevated nodule (Fig. 67.10A). At the end of the

FIGURE 67.10. Lesions of tanapox in a Congolese youth. **A:** Day 10 of rash. **B:** Day 31 of rash. (Courtesy of Z. Jezek.)

first week, the lesion is surrounded by erythema and indurated skin. Regional lymphangitis is common at this stage. During the next stage, lesions either ulcerate or become larger nodules (up to 2 cm in diameter) (Fig. 67.10B). In the African series, the maximum lesion size was usually reached within 2 weeks and then the local inflammatory response began to wane, and the lesion began to granulate. Resolution of lesions occurred within 6 weeks.⁹⁵

Most cases (78% in one series) involve a solitary nodule; however, as many as 10 lesions on one individual have been described. Most lesions (72%) occur on the lower extremities, and the fewest occur in the face and areas normally covered by clothing. Infection appears to confer lifelong immunity.⁹⁵

Diagnosis

The limited geographic distribution of tanapox virus and the patient's travel history should be considered in the diagnosis of tanapox infection. Unique clinical features that allow for the differentiation of tanapox from other orthopoxvirus infections are the nodular nature of the rash lesion, the paucity of lesions, the benign disease course, and the protracted course of rash resolution. The solid nodular/ulcerated lesions are larger and develop more slowly than those of monkeypox, but they are smaller and develop more rapidly than those of tropical ulcers.

Tanapox virus can be detected by electron microscopy, and the virions usually appear enveloped, but this finding would not exclude the possibility of infection with other morphologically similar brick-shaped poxviruses; nucleic acid testing^{50,214} on lesion extract could be used for that purpose. Tanapox virus grows in a number of cell lines (e.g., owl monkey kidney, Vero, MRC-5, BSC-1) but not on chorioallantoic membrane.

OTHER POXVIRUSES

This section discusses poxviruses of veterinary importance or of other interest.

Orthopoxviruses

Camelpox

Camelpox virus has a host range that is apparently restricted to *Camelus dromedarius*. The illness it causes is a systemic disease with generalized rash in dromedary camels. The disease is enzootic in camels. Geographically, the virus can be found anywhere in the native geographic distribution of the host in Asia and Africa. Case fatality rates as high as 28% in outbreaks have been noted,⁹⁷ young animals are more susceptible to severe disease manifestations, and extensive chains of transmission between camels could be documented. Another study in Somalia evaluated 295 cases of camelpox in 1,052 camels. The case fatality rate was highest in animals up to 1 year of age (13.5%), and only 2.8% in animals 4 years of age. The genome sequence shows a high degree of similarity with that of variola virus⁷¹; despite this and the clinical similarity of camelpox disease in camels with smallpox in humans, camelpox is generally not considered to be a zoonotic disease of humans.⁹⁷ A recent report, from India, attributes the localized lesions on the hands of camel handlers to a camelpox-like virus.¹⁸ Although virus was not isolated from the human lesions, genetic characterization of amplicons from one human lesion was similar to that of amplicons obtained from the camels' camelpox virus isolates.

Additional surveillance is needed to understand the significance of these observations.

Camelpox disease has been experimentally studied using intradermal inoculation. By day 5, papules appear at the primary inoculation site, and then form vesicles and pustules and crust by days 9 to 10. In camels, a generalized rash manifests between days 9 and 11, which is preceded by fever. The rash is most pronounced on the mouth, nose, eyes, and oral cavity. Fewer lesions are seen on the extremities. The illness can last for 2 to 5 weeks. Diagnostics historically involved evaluation of characteristic morphology on chorioallantoic membrane, in addition to electron microscopy and nucleic acid techniques. Nucleic acid PCR-based techniques are increasingly used.¹⁸

Prevention and control have been reported through the use of live-attenuated camelpox viruses.²⁰⁶ The sequences of these vaccine virus strains are not yet available, but genome restriction maps show similarity to the pathogenic strains.

Ectromelia

Ectromelia was first described in 1930.¹³³ The reservoir or natural hosts have been minimally characterized; virus has been reported from wild rodents.⁶⁹ Our epidemiologic understanding of this pathogen comes from studies of outbreaks of disease in captive mouse colonies; fundamental biological and genetic studies of this pathogen have provided a detailed understanding of factors involved in the host–pathogen interaction.

At least two forms of clinical “natural” disease may manifest. A rapidly fatal form that results in extensive necrosis of the liver and spleen and death occurs shortly after symptom onset; no rash is seen. Some animals do survive, however, and, if this is the case, a generalized rash can be seen (Fig. 67.11A). Characteristic organ pathology is imaged in Fig. 67.11B and C. A more chronic form with ulcerating lesions of the feet, tail, and snout is seen in other animals. C57Bl/6 and AKR mice are highly resistant, whereas Balb/c and other inbred species are far more susceptible. Much is known about the host genetic determinants for disease presentation, and this has been reviewed.⁵⁶

Taterapox

This virus has been isolated once in the West African country of Dahomey, now known as Benin. The virus was isolated from an apparently healthy gerbil (*Tatera kempi*) in 1968, at the time of a human smallpox outbreak. Identification as an orthopoxvirus was accomplished after liver and spleen homogenates used to inoculate suckling mouse brain induced illness, and infectivity was blocked via administration of hyperimmune vaccinia mouse ascitic fluid. The virus had biological properties most similar to those of variola alastrim minor. The sequence of the virus is closely related to that of variola.⁵⁵ Neither 1 nonhuman primate nor 12 gerbils showed signs of viral dissemination in organs after parenteral or intracerebral inoculation.¹³¹ This suggests that this orthopoxvirus has evolved to have a “successful” parasitic relationship and further suggests that other “nonpathogenic” orthopoxviruses exist.

North American Orthopoxviruses

Raccoonpox, skunkpox, and volepox are the North American orthopoxviruses. In general, these too have been isolated from fairly asymptomatic animals or animals with localized lesions. The viruses have been propagated in monkey kidney cell lines; A-type inclusions are evident, whereas full genome sequence

FIGURE 67.11. Lesions of mousepox in mice. **A:** The generalized rash in a susceptible hairless nonathymic mouse. **B:** Swelling and necrosis of liver and spleen and hemorrhagic intestine in a susceptible mouse that died prior to appearance of rash. **C:** Histologic appearance of necrotic liver. (A courtesy of Zentralinstitut für Versuchstiere, Hanover, Germany; B and C from Allen AM, Clarke GL, Ganaway JR, et al. Pathology and diagnosis of mousepox. *Lab Anim Sci* 1981;31:599–608.)

information is not yet available. Raccoonpox was identified in the upper respiratory tissues of 2 of 92 healthy-appearing raccoons trapped in Maryland. Twenty-two of these animals appeared to have orthopoxvirus seroreactivity.¹¹¹ Volepox was isolated from a skin lesion on a vole (*Microtus californicus*) in the San Francisco Bay Area of California; serosurveys of voles suggested the virus was enzootic. Experimental infection of seronegative voles demonstrated development of a localized lesion and antiorthopoxvirus seroconversion after challenge via footpad or tail inoculation.^{167,209}

Capripoxviruses

The capripoxviruses are somewhat larger, by electron microscopy, than other poxviruses with dimensions of $300 \times 270 \times 200$ nm. A number of strains of each species have been sequenced; the genome is ~154 kbp. Three species of capripoxvirus have been categorized. The diseases sheeppox, goatpox, and lumpyskin are caused by the viruses of similar names (Table 67.1). Representative strains of these viruses have been sequenced.

Lumpyskin disease was first identified in 1929 in Zambia; the virus infection has largely remained restricted to the African continent¹⁴⁸ but has emerged in the Middle East. Illness consistent with sheeppox is recorded as early as 2 AD.¹⁶⁴ Reports of goatpox were first made in Norway in 1879. Sheeppox and goatpox diseases are considered to have a significant impact on domesticated animals. Geographically, they currently cause disease in Southwest Asia, on the Indian subcontinent, and in central and northern Africa. There is increasing concern for the agricultural and economic impact of this emerging infectious disease.⁷

Transmission of lumpyskin disease is mechanical through arthropod bites; virus has been detected in two species of biting flies, and one of these, the stable fly (*Stomoxys calcitrans*), has been shown capable of transmitting disease.¹⁴¹ The reservoir host is postulated to be the African Cape Buffalo. Experimentally infected young buffalo and wildebeest failed to show disease or a rise in antibody titers after infection.²¹² However, LSDV seroprevalence in wild-caught buffalo has been low.⁴⁶ Within susceptible species, *Bos taurus* and *Bos indicus* mortality

is usually 1% to 2%. Transmission of sheeppox and goatpox within domestic flocks is considered to be airborne¹⁶⁴; additional evidence supports mechanical arthropod transmission by *S. calcitrans*. Scabs contain infectious material for months permitting fomite transmission. Sheeppox and goatpox are notifiable diseases in many countries. The spread of disease within a flock can infect up to 75% of the animals. Morbidity and mortality is highest in young animals and in lactating females, and overall mortality rates of 10% to 58% are reported.

Lumpyskin disease primarily affects species *Bos taurus* and *Bos indicus* and presents with a febrile prodrome followed, 10 days later, by cutaneous manifestations and lymphadenopathy. The skin lesions initially appear as raised nodules in the dermis and epidermis, which subsequently ulcerate and can become superinfected. In the oropharynx and mucosal surfaces, the nodules appear yellow-gray. Edema of the extremities and lymphadenitis are associated features. Recovery is slow, lasting up to 1 month.

Generally, sheeppox and goatpox are host (sheep and goat, respectively) specific, although clinical disease symptoms have been reported in both species during some outbreaks. An asymptomatic incubation period of 1 to 2 weeks is followed by febrile prodrome (up to 108°F) of mucosal swelling of the eyelids and mucosal discharge from the nose. Decreased appetite and occasionally arched back stance is noted. One to 2 days following prodromal symptoms, generalized appearance of ~1-cm lesions over the corpus develop (Fig. 67.12A and B), which progress through macular, papular, vesicular, and pustular stages; these are most obvious on areas with the least amount of hair. The lesions persist for 3 to 4 weeks and eventually scab over. Generalization of rash is more pronounced in young animals ages 4 to 5 months than it is in adult animals. Oral lesions ulcerate, and, in some animals, lesions in the lower respiratory tract are seen.

Diagnosis of capripoxvirus infections is often made on a clinical basis; differential diagnosis of lumpyskin disease includes consideration of bovine herpesvirus 2. Control strategies have largely used vaccination. Sheeppox and goatpox viruses can be grown in primary culture from ovine bovine or caprine sources. Cytoplasmic inclusion bodies are characteristic. Additional laboratory diagnostics, including enzyme-linked

FIGURE 67.12. Infections of domestic animals with poxviruses of other genera. Capripoxvirus infection in sheep (A) (sheepox) and in goats (B) (goatpox). immunosorbent assay (ELISA) and PCR-based techniques, are available and have been reviewed.¹⁶⁴

Prevention and control of capripoxvirus disease involve vaccination strategies. For lumpyskin diseases, strategies have included the use of sheepox or goatpox, attenuated by tissue culture passage, or an attenuated strain of lumpyskin disease virus (strain Neethling). A review of the epidemiology and vaccination control issues is available.⁸⁷ Control of sheepox and goatpox disease has been attempted with live-attenuated and inactivated viral vaccines. However, inactivated vaccines provide only short-term protection, and the safety of live-attenuated vaccines is questionable; they can cause generalized disease and death in some animals.

Suipoxvirus

Suipoxvirus is an episodic viral disease of pigs with worldwide distribution; the swinepox genome has been sequenced. The

virus is currently the sole member of the *Suipoxvirus* genus and is phylogenetically most similar to species of the *Capripoxvirus* genus. Clinical disease can be heralded by low-grade fever, followed by papules, which over the course of 1 to 2 days per stage of development, progress to vesicles and pustules with umbilication (Fig. 67.12C). Crusting and scabbing of lesions ensues over the following 7 days. The duration of clinical disease can be 3 weeks. Mechanical transmission of disease between pigs occurs via the pig louse (*Haematopinus suis*). Disease control is provided by appropriate hygienic animal husbandry practices and control of the louse population.

Leporipoxvirus

The Leporipoxvirus virions are brick shaped, with a size of $300 \times 250 \times 200$ nm. Genome size is ~160 kbp and is 40% G+C in content. The viruses can infect multiple tissue culture cell lines. Myxoma virus is an obligate rabbit pathogen that demonstrates features that typify a general understanding of the distinction between reservoir host species and nonreservoir-susceptible species. Viral infection results in a localized “fibroma” infection in its reservoir species (Fig. 67.12D); the South American rabbit (*Sylvilagus brasiliensis*); causes a systemic, lethal disease in nonreservoir European rabbits (*Oryctolagus cuniculus*); and has coevolved with this new host. After intentional introduction of myxoma to control feral rabbit populations in Europe and Australia (the susceptible nonreservoir hosts), initial success of the program resulted in 99% mortality; however, milder virus variants emerged, and the surviving rabbits became more resistant to the effects of infection.⁶⁰

In species susceptible to generalized disease, the illness proceeds along an aggressive course. Early clinical signs of illness are blepharoconjunctivitis and swelling of the muzzle and anogenital regions; symptoms are fever and listlessness. Within 48 hours of development of clinical signs and symptoms, animals can die; if they survive past this time point, the classic myxomas, subcutaneous swellings, develop (Fig. 67.12E). The disease is mechanically transmitted by arthropod vector bites or experimentally by intradermal injection; it can also be transmitted by droplets.

The pathogenesis in nonreservoir species follows deposition of virus into the dermis. Virus replicates in major histocompatibility complex (MHC)-II dendritic-like cells and moves, within cells, to the draining lymph node within 24 hours to replicate in the lymph node,¹⁹ and then disseminates to the epidermis of the skin, lung, testis, and spleen. Virus from the primary lesion also moves to epidermis. A number of myxoma genes have been characterized to affect virulence and disease pathogenesis, usually via inflammatory and immune response modulation, and have been reviewed.^{8,9,215} Proteins are expressed that modulate TNF, γ -IFN, and chemokines; bind CC chemokines; and inhibit apoptosis.

The fibroma viruses cause small, localized tumors—the fibroma. The host range (Table 67.1) is restricted. To date, rabbit fibroma, squirrel fibroma, and hare fibroma diseases are described, caused by rabbit fibroma (also called Shope fibroma), squirrel fibroma, and hare fibroma viruses, respectively. These have been reviewed.⁹

Control and prevention of disease is facilitated through immunization. Vaccination and protection of rabbits from myxomatosis can be provided using a related species, fibroma virus, or through the use of attenuated myxoma viruses.

Avipoxvirus

The virions of the *Avipoxvirus* genus are brick shaped, with dimensions of $330 \times 280 \times 200$ nm. The genome size is one of the largest, about 300 kbp. There are a large number of avipoxviruses, mostly described by the avian species where infection has been evident to cause illness. The viruses do not cause illness or true replicative infection in mammalian hosts or mammalian cell lines but are able to present antigen to the immune system. For this reason, some have become important research vaccine vehicles. Currently, the ICTV classifies a number of avipoxvirus species: fowlpox virus, canarypox virus, juncopox virus, mynahpox virus, psittacinepox virus, quailpox virus, sparrowpox virus, starlingpox virus, turkeypox virus, and pigeonpox virus. Unclassified members are penguinpox virus, peacockpox virus, and crowpox virus.

The disease fowlpox has been best characterized. Two forms of disease manifest, and it is likely that the different manifestations are due to different routes of exposure. The first to be described manifests with largely cutaneous manifestations on the comb, wattles, and around the beak; other lesions can be evident on the limbs and cloacae. Most likely, disease results via the mechanical transmission of virus from a biting arthropod to the fowl. The lesions that develop are nodular and yellowish, and can coalesce and present a nidus for secondary bacterial infection. Lesions usually resolve in 3 weeks. Avian species with large combs are more susceptible to this form of disease than those with small combs. The other form of fowlpox has also been referred to as “diphtheric” disease. Transmission is likely via respiratory droplets between members of a flock in proximity. The infectious lesions present in the mucosal surfaces of the airway, and can coalesce to create a pseudomembrane and cause death by asphyxiation. Mortality is usually low in healthy flocks, but in flocks under stress, such as those that are egg laying, mortality can range to 50%.²²

HISTORY

Highly transmissible liver disease has been known for several thousand years. A major cause is hepatitis A virus (HAV), a picornavirus that infects the liver and is shed in feces. Evidence for a distinct form of hepatitis, transmitted from blood and body fluids, began appearing in the nineteenth and early twentieth centuries. This second form was finally accepted following outbreaks of hepatitis after vaccination for measles, mumps, and yellow fever in the 1930s and 1940s. These vaccines all contained convalescent serum or plasma, or human serum added as a “stabilizer,” which inadvertently contained an infectious agent. Plasma, blood transfusions, and repeated use of nonsterile needles were also identified as causes of hepatitis outbreaks, and the disease was shown to have a viral etiology (reviewed in 28,268,815). Originally identified as hepatitis B or serum hepatitis, distinct from the disease caused by hepatitis A virus, this newly recognized entity was later discovered to be two separate diseases. Once tests were available for hepatitis B virus (HBV), a unique DNA virus discovered during the 1960s, it became clear that there was a second form of serum hepatitis, thereafter called nonA nonB hepatitis. A virus with structural similarities to flaviviruses was identified in the late 1980s as the major cause of nonA nonB hepatitis, and named hepatitis C virus (HCV).^{11,60,122,123,128}

The discovery of HBV came by an indirect route. To identify and track genetic differences in human populations, Blumberg and colleagues were using sera from multiply transfused individuals as sources of antibody to human serum proteins. The idea was that these sera would contain antibodies that bound to proteins differing in sequence from those of the transfusion recipients. During the course of these studies a new antigen, named “Australia antigen,” was identified in serum from an Australian Aborigine.⁴⁷ Because this antigen was found to be common in leukemia patients and in Down syndrome patients, who have a high risk of leukemia, it was hypothesized that the antigen predicted leukemia risk. However, a Down syndrome patient initially negative for Australia antigen was observed to seroconvert, and seroconversion was correlated with a mild case of hepatitis. At about the same time, a member of Blumberg’s laboratory experienced a mild case of hepatitis following contact with contaminated material, again with the appearance of Australia antigen in the blood.^{48,50}

The Australia antigen was quickly associated with serum hepatitis in a wider group, including a significant fraction of post-transfusion hepatitis cases.⁵¹⁰ At the time, post-transfusion hepatitis occurred in at least 10% to 30% of multiply transfused individuals.^{9,10,339,340,346,558,631} Screening blood banks for

contaminated blood (Australia antigen-positive) resulted in an approximately twofold decline in the incidence of post-transfusion hepatitis. The remaining cases were mostly due to HCV. For this discovery Blumberg received the Nobel Prize in Medicine in 1976.⁴⁶

The ability to carry out retrospective studies with assays for Australia antigen confirmed a long-held suspicion that HBV was responsible for a chronic hepatitis leading to cirrhosis and liver cancer in many parts of the world.^{49,215,428,479,484,560,638,644,673,696,710,738,741,742} The Australia antigen, purified from the serum of infected individuals, also proved to be an effective vaccine, with greater than 90% efficacy in inducing an antibody response in adults. However, universal vaccination still remains a goal rather than accomplished fact. The World Health Organization (WHO) estimates there are now 400,000,000 individuals worldwide who are chronically infected with HBV, 25% of whom will die of chronic liver disease or hepatocellular carcinoma.

Electron microscopic (EM) studies revealed that Australia antigen is carried by spherical particles, with a diameter of

~22 nm, and to a lesser extent, by ~22-nm, rod-like particles (Fig. 68.1). Sera contain a much smaller amount of spherical virus particles with a diameter of approximately 42 nm, termed the Dane particle.¹⁴⁹ Australia antigen is a component not just of the 22-nm particles but also of the virus envelope.²⁵⁸ Treatment with nonionic detergent releases a spherical particle from virus, the viral capsid, with a diameter of approximately 27 nm. Robinson and colleagues showed that the capsids contain a circular viral DNA of about 3000 base pairs (bp), as well as an endogenous DNA polymerase activity that synthesizes virus DNA when virions are treated with nonionic detergent and incubated in the presence of dNTPs.^{314,585–587} Summers showed that the circular conformation is maintained by a short cohesive overlap between the 5' ends of the two DNA strands and that the circle is only partially double stranded, one strand being incomplete. This incomplete strand is extended and the single-strand gap is at least partially filled in by the endogenous DNA polymerase.⁶⁷⁴

The endogenous DNA polymerase activity facilitated the discovery of several HBV-like viruses (Fig. 68.2) including woodchuck hepatitis virus (WHV) in eastern woodchucks (*Marmota monax*),^{646,677,678,695,727} duck hepatitis B virus (DHBV) in domestic ducks in China (Summers, personal communication; 749, 807) and the United States,⁴⁴⁵ and ground squirrel hepatitis virus (GSHV) in Beechey

FIGURE 68.1. Cryo-electron microscopy of viral particles from a chronically infected patient. **A:** 42-nm Dane particles, and 22-nm filamentous and spherical subviral particles are seen. **B** and **C:** Dane particles with compact and gapped morphology, respectively. **D:** Particles with mixed morphology. Gapped areas are delineated in white. (Adapted from Seitz S, Urban S, Antoni C, et al. Cryo-electron microscopy of hepatitis B virions reveals variability in envelope capsid interactions. *EMBO J* 2007;26:4160–4167, with permission.)

FIGURE 68.2. Detection of hepatitis-B like viruses using an endogenous DNA polymerase assay. Serum samples from a woodchuck and duck were centrifuged to pellet virus. The pellet was suspended in a DNA polymerase reaction cocktail containing radiolabeled nucleotides and incubated at 37°C. SDS-pronase was then added, and after digestion at 37°C to free DNA from protein, the products were subjected to gel electrophoresis in 1.5% agarose. Radiolabeled DNA was detected by autoradiography. The marker is bacteriophage lambda DNA digested with the restriction endonuclease Hind III. Woodchuck hepatitis virus (WHV) DNA migrates faster than duck hepatitis B virus (DHBV) DNA because the incomplete strand of WHV was only partially filled in by the endogenous DNA polymerase reaction.

ground squirrels (*Spermophilus beecheyi*).⁴³⁵ Hepatitis B-like viruses closely related to the original isolates were later identified in Richardson's (*Spermophilus richardsonii*),^{467,694} and arctic ground squirrels (*Spermophilus parryi kennicotti*),⁶⁹⁹ ducks,^{236,430,728} wild mallards,¹³⁵ geese,^{98,236} cranes,⁵⁵⁷ storks,⁵⁶⁵ and herons,⁶⁵¹ but the three original nonprimate animal models—particularly the woodchuck and the domestic duck—have been the mainstay of hepatitis B research for the past 30 years.

HBV itself is found in all apes, including chimpanzees, gorillas, orangutans, and gibbons.^{280,358,422,500,584,601,658,685,707,740,753,816} These isolates are closely related in sequence to human HBV and human isolates were shown to infect chimpanzees and gibbon apes.^{20–22,39,40,157,270,615} At present, these primate isolates are considered subtypes of HBV rather than distinct species. Only the chimpanzee has seen significant use as an experimental model, though for ethical reasons as well as cost its use has been limited. A primate virus closely related to HBV has also been isolated in the New World from the woolly monkey.^{357,356} This virus, woolly monkey hepatitis B virus (WMHV), differs in host range from HBV and has been designated the prototype for a new species of hepatitis B-like virus.¹⁸²

CLASSIFICATION OF VIRUSES WITHIN THE HEPADNAVIRUS FAMILY

All of these hepatitis viruses share remarkable similarities in genome organization and replication strategy and, with the *Spumaviridae* (foamy viruses) (see Chapter 52), are the only DNA viruses of animals known to replicate their DNA by reverse transcription of a viral RNA. Collectively, the hepatitis B-like viruses are assigned to the family *Hepadnaviridae* (hepatitis DNA virus), for which (human) HBV is the prototype. This family contains two genera, the orthohepadnaviruses, infecting mammals, and the avihepadnaviruses, infecting birds.¹⁸² A maximum sequence divergence of about 40% is found among the orthohepadnaviruses,^{207,618} compared to about 20% among avihepadnaviruses.²³⁶ Designation of the *Hepadnaviridae* as a new family of viruses is based on the extremely small size of the viral genomes (3–3.3 kbp), the novel arrangement of open reading frames, and the unique replication strategy, differing almost completely from other viruses replicating by reverse transcription. Assignment to two genera is based on the strong DNA sequence similarities among all orthohepadnaviruses, and all avihepadnaviruses, but an almost complete lack of homology between the two groups (Fig. 68.3).

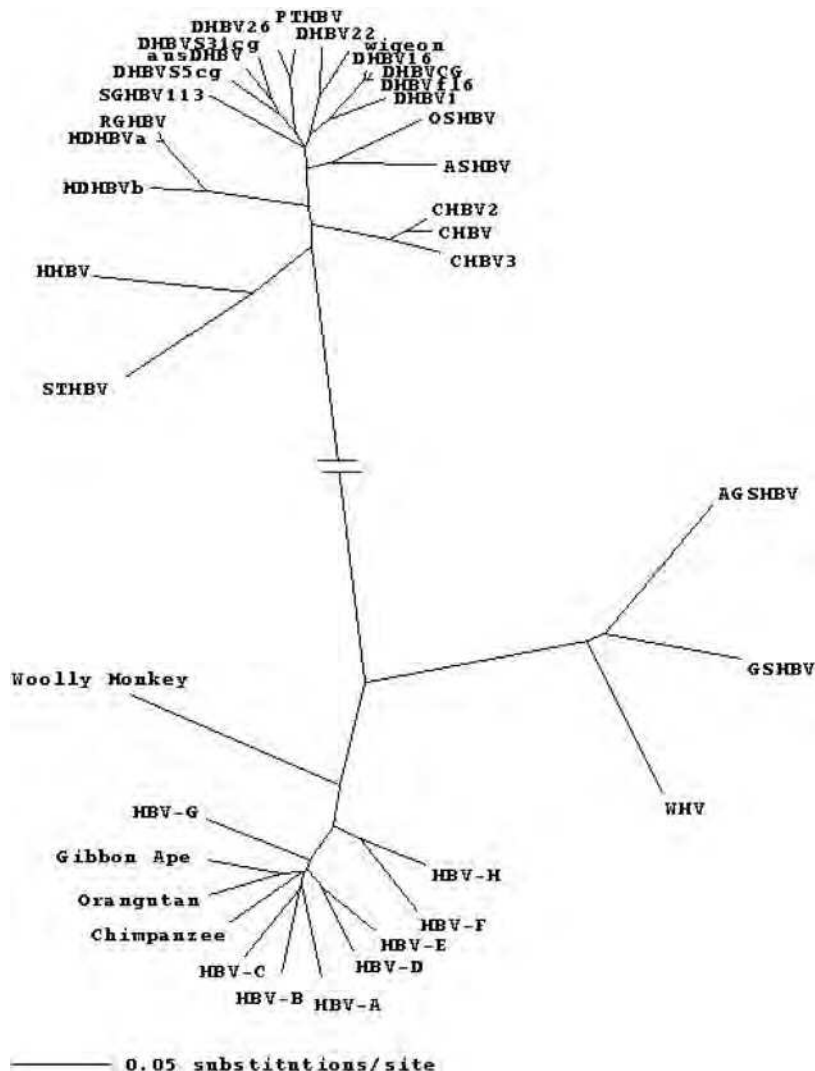

FIGURE 68.3. Phylogenetic tree of avi- (top) and ortho- (bottom) hepadnaviruses. A dendrogram file constructed using ClustalX was displayed by Treeview.

Assignment to separate species within the two genera has been based primarily on differences in viral host range, which has also been associated with differences in sequence. Two species have been assigned in the avihepadnavirus group, DHBV and heron hepatitis B virus (HHBV). Most newer isolates are as yet unassigned.^{182,236} Where sequence and host range data are available, orthohepadnavirus species have also been assigned. These species include HBV, WHV, GSHV, and WMHV.

With the availability of polymerase chain reaction (PCR)-based assays, numerous studies have been performed to gain information on the number and geographic distribution of HBV genotypes and naturally occurring HBV mutants infecting humans. Eight HBV genotypes, A to H, have been identified,^{15,206,499} with isolates belonging to different genotypes showing pairwise differences greater than 8% and less than 17%. A ninth genotype, I, has been proposed but remains controversial as the divergence is about or slightly less than 8%, with a close relationship of half the I genome to genotype C HBV.^{515,793} An isolate possibly defining a tenth genotype, J, has also been described.⁶⁸⁹ Distinct genotypes have also been found in great apes. Different genotypes tend to have distinct geographic distributions and possibly distinct clinical manifestations (Fig. 68.3).

VIRION STRUCTURE

HBV is a spherical virus with an outer diameter of approximately 42 nm (Fig. 68.1). The inner shell of the virus has a diameter of ~22 nm and is made up of 120 dimers of the core protein. The dimers form the icosahedral capsid with a triangulation number $T = 4$. A small fraction of capsids consists of only 90 dimers with a triangulation number $T = 3$.^{55,132,140,167,772} It is not known whether virions with the smaller capsids are infectious or represent

dead-end products caused by an aberrant assembly process. The capsid is covered with a lipoprotein membrane made up of three forms of the viral envelope protein, large (L), middle (M) and small (S) (Fig. 68.4), acquired together with host lipids during budding into multivesicular bodies (Fig. 68.5). The L, M, and S proteins are present in the virus envelope at a ratio of about 1:1:4.²⁵⁸ A model based on the analyses of virions and capsids by electron cryomicroscopy (cryoEM) predicts that $T = 4$ capsids carry 180 dimers formed by envelope proteins.^{167,621} The proportions of homo- and heterodimers is unknown. Notably, virions from patient sera exhibit morphologic variation: they appear either as compact or as gapped particles, which differ in the distance between the capsid and membrane⁶²¹ (Fig. 68.1). Capsids contain a single copy of the partially double-stranded DNA (dsDNA) genome, which is covalently linked to the viral reverse transcriptase (RT) at the 5' end of the complete strand (Fig. 68.6). RT provides the endogenous DNA polymerase activity, discussed earlier^{314,674} (Figs. 68.2 and 68.6). There is also evidence for the presence of cellular proteins including one or more serine kinases within the virus.⁷ The virus has a buoyant density of 1.24 to 1.26 g cm⁻³ in CsCl and an $s_{20,w}$ of 280S. The titers of HBV can vary significantly among patients, ranging up to 10¹⁰ per ml in blood.

As noted earlier, HBV infections also lead to the production of noninfectious subviral particles. The 22-nm spheres can reach titers as high as 10¹² per ml and represent the most abundant particle released into the blood from infected liver cells. CryoEM studies of isometric particles isolated from sera of transgenic mice revealed that they have an octahedral symmetry, different from the icosahedral structure of Dane particles.³²⁵ These spheres are composed of 48 dimer subunits that assemble into two classes of particles that differ in size, presumably caused by the heterogeneity of the subunits. Spheres contain M and S proteins at a ratio of about 1:2 and only trace amounts

FIGURE 68.4. Model of HBV virions. A: HBV virion with a $T = 4$ icosahedral capsid (blue) with 120 spikes and an outer envelope with protein projections. **B:** X-ray crystal structure of a capsid docked into the cryo-electron microscopy density map of the virion capsid (left). S, M, and L refer to the three envelope proteins described in the text. Amino acids around the base of the spikes in core proteins, which are important for envelopment of core particles, are shown in green.^{370,522} (From Dryden KA, Wieland SF, Whitten-Bauer C, et al. Native hepatitis B virions and capsids visualized by electron cryomicroscopy. *Mol Cell* 2006;22:843–850, with permission.)

FIGURE 68.5. Model for the life cycle of hepadnaviruses, as described in the text.⁵²² Envelope proteins are shown in *green*, DNA-containing capsids in *blue*, and RNA-containing capsids in *red*. Early in infection, when envelope protein concentrations are low, capsids enter the CCC DNA amplification pathway. Envelope proteins enter the endoplasmic reticulum and assemble into subviral particles (SVP) or transfer to MVBs where virion assembly is believed to occur. Mature virions might exit cells through exosomes (for details and references see the text).

of L.²⁵⁹ The rod-like particles (tubes, filamentous particles) contain approximately equal amounts of M and L. Their surface exhibits spike-like features composed of homo- and heterodimers of L, M, and S proteins which, like virus, are in the ratio 1:1:4, with a diameter of about 22 nm.⁶³⁵ However, in contrast to octahedral isometric particles, tubes isolated from patient sera do not have an ordered structure.⁶³⁵ Subviral particles contain 40% lipid and sugar by mass and have a buoyant density of 1.18 g cm⁻³ in CsCl. Their exact role in the HBV life cycle is not known. One possibility is that, by adsorbing virus-neutralizing antibodies, they facilitate virus spread and maintenance in the host.

GENOME STRUCTURE AND ORGANIZATION

The structure of the HBV genome and organization of open reading frames on viral DNA is shown in Figure 68.6. All of the ORFs are in the same direction (clockwise in this illustration), defining minus and plus strands of viral DNA. Within virions, minus-strand DNA is complete and spans the entire genome, in contrast to plus strands, which extend to

about two-thirds of the genome length and have variable 3' ends.^{420,674} In this regard, avihepadnaviruses differ from orthohepadnaviruses because they normally extend plus strands almost all the way to the location of the modified 5' end.⁴⁰⁰ The primers of both plus- and minus-strand DNA synthesis remain attached throughout virus maturation. Minus strands are covalently linked to the viral reverse transcriptase through a phosphotyrosine bond. Plus strands contain a short RNA oligomer derived from the 5' end of pregenome (pg) RNA, the template for minus-strand DNA synthesis. Minus strands exhibit a small 8- to 9-nucleotide-long terminal redundancy, termed *r*, which is required for the formation of relaxed circular (RC) DNA during plus-strand DNA synthesis.^{400,617,764} A small fraction (5%–20%) of virus contains double-stranded linear (DSL) DNA in lieu of RC DNA, a consequence of *in situ* priming of plus-strand DNA synthesis.⁶⁵⁷ Virions with DSL DNA are infectious, but can lose important sequences from their ends during initiation of infection and appear, therefore, to play only a minor role in hepadnavirus replication.^{782,784}

The genetic organization of HBV is complex. The genome contains four promoters, two enhancer elements, and a single polyadenylation signal to regulate transcription of viral RNAs.

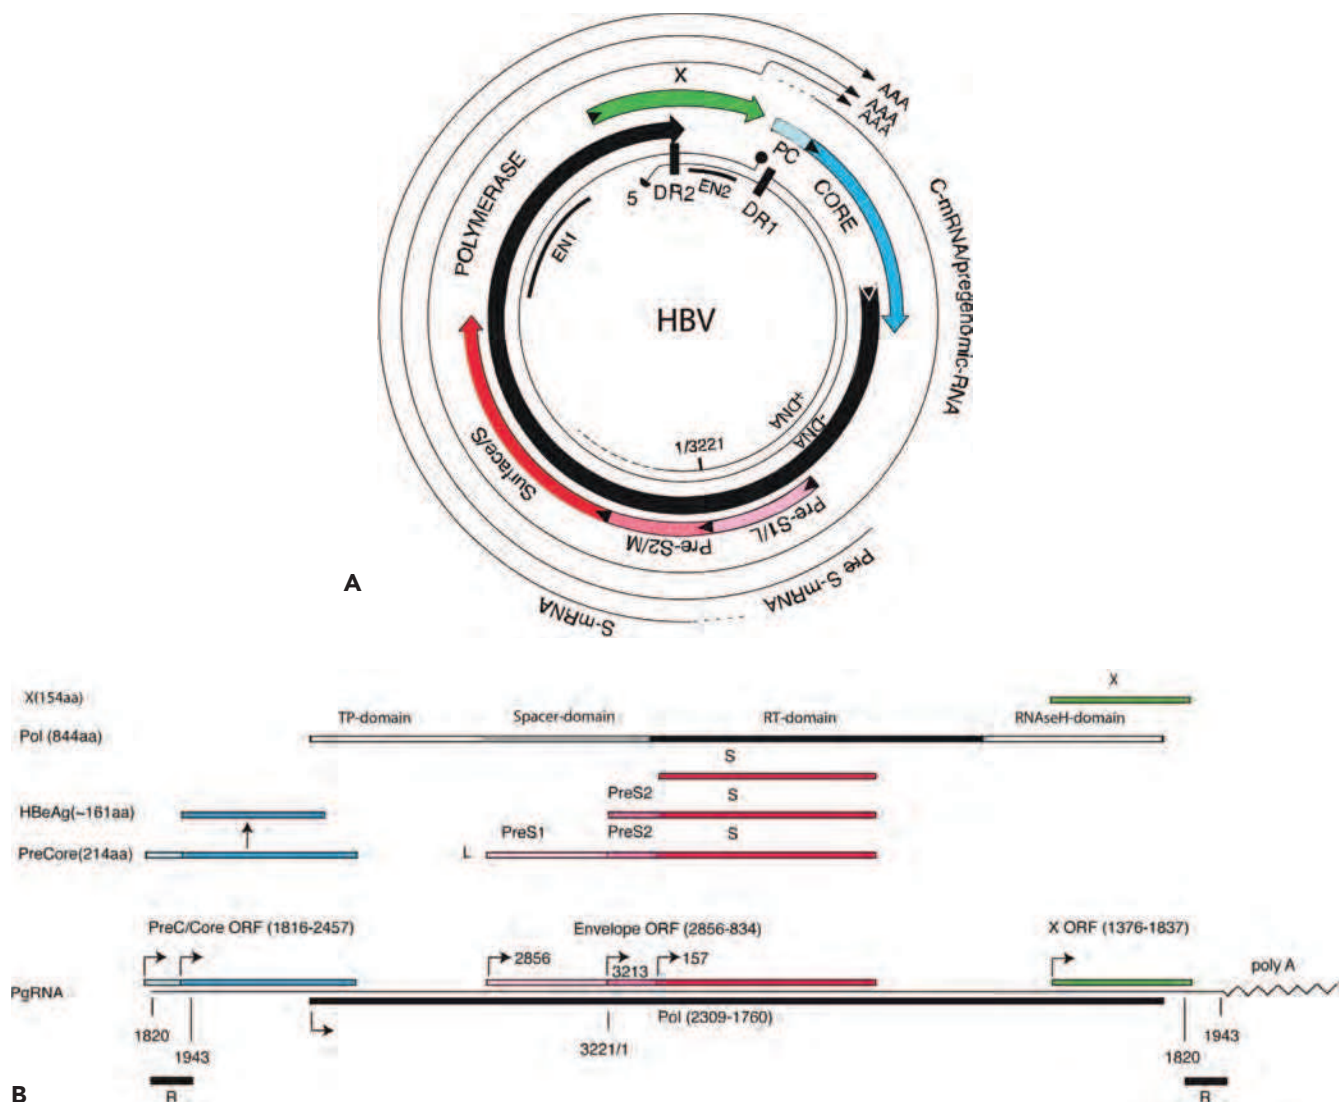

FIGURE 68.6. Genome structure and organization. The relaxed-circular DNA genome of HBV with a complete minus strand and incomplete plus strand is shown in **A** (inner circle), along with the major mRNAs, all of which end at a common polyadenylation signal located in the core open reading frame. All open reading frames have a clockwise direction. The single-stranded gap in the plus strand is filled in by the viral RT, which is covalently attached to the 5' end of minus-strand DNA. The proteins produced from each open reading frame are illustrated in **B**, using pgRNA, a terminally redundant mRNA that is reverse transcribed to produce viral DNA, as a map reference. Map coordinates are from the sequence reported by Valenzuela et al.⁷³⁵ (accession number X02763), with numbering from a unique EcoRI restriction endonuclease site. R, large terminal redundancy; pgRNA, pregenomic RNA; DR, direct repeat; EN, enhancer, PRE, post-transcriptional regulatory element.

In addition, there are four open reading frames and several *cis*-acting signals required for viral DNA replication (Fig. 68.6). All viral transcripts are encoded by the minus strand, and are capped and polyadenylated. Transcription regulatory regions are present within open reading frames and are active following the transport of the genome into the cell nucleus, where it is converted into a covalently closed circular DNA form, called CCC DNA.

The major transcripts that are detected by Northern blot analyses of HBV-infected livers are 3.5 kb, 2.4 kb and 2.1 kb in length and termed pre-C/C, pre-S and S messenger RNAs (mRNAs), respectively.^{90,175} In addition, a minor transcript,

X mRNA, about 0.7 kb, has occasionally been detected in infected tissues and more consistently in cells transfected with subgenomic HBV DNA.^{221,599,717} The existence of an X mRNA would provide the most plausible mechanism for the translation of this gene, although internal initiation of translation from pre-C/C RNAs, pre-S or S mRNAs cannot be excluded as alternative mechanisms. Avihepadnaviruses express three major transcripts analogous in length to the three major mRNAs of mammalian hepadnaviruses.⁷⁸ All hepadnavirus transcripts share a common 3' end created by a polyadenylation signal located in the core gene. Fine mapping of the 3.5-kb preC/C mRNAs revealed three different 5' ends bracketing the initiation codon

of the pre-C gene, indicating that translation of the overlapping pre-C and core genes occurs from separate transcripts (Fig. 68.6).^{90,175} The two longer RNAs, beginning upstream of the pre-C initiation codon, are referred to as pre-core (pre-C) mRNAs and the shorter, beginning downstream, is pregenome RNA. PgRNA is the template for the translation of the core and RT proteins and, as the name indicates, is also the template for viral DNA synthesis via reverse transcription. In contrast, the function of the pre-C mRNAs appears to be limited to the translation of the pre-C gene. As with the large, terminally redundant mRNAs, S mRNAs also have heterogeneous 5' ends flanking the initiation codon of pre-S2 and, hence permitting the translation of either the M or S protein.^{89,656} The third major transcript, pre-S, has a unique 5' end and supports the translation of L. The 5' end of X mRNA is heterogeneous.⁷⁷⁵ In addition to the four promoters, two enhancers, EN1 and EN2, regulate transcription of the viral RNAs (Fig. 68.6).

The core protein is a cytoplasmic, basic phosphoprotein with a molecular weight (MW) of 21 kd that assembles into subviral capsids. Early on, its antigenicity was recognized and diagnostic assays to monitor ongoing or resolved infections were developed. The pre-C protein is best known by its serologic name: e-antigen, or HBeAg. Although the pre-C gene includes the entire core protein open reading frame and upstream coding sequences, the polypeptide is shorter than the core protein due to posttranslational processing, and has a MW of only 15 kd. The mature pre-C protein exhibits distinct antigenic properties from the core protein. Pre-C does not play a role in viral replication, but might exert a role in the regulation of the immune response against HBV, particularly against the core protein.¹⁰⁹ HBeAg is an important diagnostic tool that can be used to determine the status of ongoing HBV infections.

The *pol* gene encodes the viral DNA polymerase, which is the sole enzyme encoded by hepadnaviruses. It consists of three functional domains and a hinge region, known as the “spacer,” and has an MW of about 90 kd. The N-terminus encodes the terminal protein (TP) domain, which acts as the primer for minus-strand DNA synthesis. The C-terminal region encodes the reverse transcriptase and RNaseH (RT) domains.

The PreS/S genes overlap the hinge region and RT domains of the *pol* gene, albeit in a different reading frame. They encode three integral transmembrane envelope glycoproteins with distinct N-terminal domains. The shortest, the S protein, is the most abundant envelope protein in virions and in the subviral spheres and rods. It contains the major antigenic determinants of Australia antigen, which led to the discovery of HBV and provided the reagent for the development of diagnostic tools for the detection of HBV infections and of vaccines against HBV infections.⁴⁶ A fraction of S protein is modified by asparagine (N)-linked oligosaccharides, increasing the MW of the protein from 24 to 27 kd.^{437,543} The 31-kd M protein represents a larger form of HBsAg with a 55 amino acid N-terminal, glycosylated extension, referred to as PreS2, translated from an in-frame initiation codon. It represents about 10–15% of total envelope proteins in infected cells. A specific function for this protein is not yet known, as it is not essential for virion assembly.⁷³ Recent studies suggest that the 55 amino acids that distinguish M from S may serve primarily a spacer function between S and the PreS1 domain of L.⁴⁹³

The 42 kd L protein is a myristoylated polypeptide translated from the first initiation codon of the PreS/S open reading

frame.⁵³⁹ The extra amino acids at the N-terminus, relative to M, define the PreS1 domain. Although it represents only 1% to 2% of total surface proteins in infected cells, L is enriched in virions, where it represents approximately 17% of the envelope proteins.²⁵⁸ In contrast, subviral particles are primarily composed of M and S proteins. Consistent with its distribution, L protein provides the primary ligand for the viral receptor. In contrast to the mammalian hepadnaviruses, avihepadnaviruses encode only two nonglycosylated envelope proteins, corresponding to L and S of HBV. DHBV subviral particles are pleomorphic, roughly spherical, with diameters ranging from 35 to 60 nm,⁴⁴⁵ as compared to the ~40-nm DHBV virion.

The smallest viral gene, found exclusively in mammalian hepadnaviruses, encodes HBx or X with a MW of 17 kd. DHBV has been reported to express an X-like protein,⁹⁹ but a functional significance for this ORF was not supported by *in vivo* studies.⁴⁵⁵ The X gene overlaps, in a different reading frame, the C-terminal portion of the polymerase and two transcriptional control elements, EN2 and core promoter. X is predominantly a soluble cytoplasmic protein with a short half-life in the range of 15 to 20 minutes.^{147,148,166,260,605} However, it has also been found associated with the cytoskeleton³⁶³ and in the nucleus.^{54,166,260} Modifications of the protein (phosphorylation, acetylation) have been observed under selected cell-culture conditions,^{378,732} but not yet in infected liver tissue. Except for the spacer region in the polymerase, X is the least conserved hepadnavirus protein. While X is required for efficient infection *in vivo*,^{106,804,814} its exact role in the viral life cycle is not known. Since the report that HBx has transcription factor-like activity,^{649,726} experiments in tissue culture cells revealed many other functions of HBx that will be summarized later in this chapter.

STAGES OF REPLICATION

Infection of Hepatocytes

The mechanisms by which HBV and other hepadnaviruses infect hepatocytes are still not well understood. Efforts to investigate this problem have been hampered by the lack of widely available cell lines that are permissive for infection. As a consequence, studies have been limited to the use of primary hepatocyte cultures (PHC) that typically remain susceptible to infection for only a few days following their preparation from liver tissue,^{8,225,503,725} or to a cell line that, under extreme culture conditions, becomes susceptible to HBV.²²⁶

Investigations into the identification of envelope components that play a role in infection revealed that the PreS1 domain of L has a critical role. The most compelling results stem from genetic experiments with chimeric envelope proteins between closely related hepadnaviruses that exhibit different host-range specificity, such as DHBV and its close relative, heron hepatitis B virus (HHBV), or HBV and WMHBV.^{124,292} These studies revealed that the specificity of these viruses for their cognate hepatocytes segregates with the N-terminal half of the PreS1 domain. Consistent with these observations, infectivity of DHBV and HBV can be neutralized by anti-PreS1 antibodies,^{114,354} and infection of hepatocytes can be blocked by peptides homologous to portions of the PreS1 region of the L protein.^{224,542,731} A study with hepatitis delta virus (HDV, Chapter 69), a viroid-like satellite of HBV that requires HBV envelope proteins to infect hepatocytes, provided evidence that

a second determinant, mapping to the external hydrophilic loop of the S protein is required for infectivity.²⁹⁸ More recent work with HBV confirmed this finding. It remains unclear how this determinant functions during infection of hepatocytes.^{44,600}

Infection of duck hepatocytes by DHBV has been intensely studied. It is a slow process that takes place over a period of at least 16 hours.^{564,682} Internalization rather than binding to the receptor appears to be the rate-limiting step because the latter can rapidly occur at 4°C. An estimated 10⁴ receptors with high-affinity binding sites for DHBV are present on primary cultures of duck hepatocytes.^{326,562}

Infection by DHBV and HBV is most likely pH independent because it can occur in the presence of lysosomotropic agents or after pretreatment of virus at low pH.^{246,328,580} Moreover, for DHBV, infection may depend on a conserved peptide translocation motif (TLM), which is located near the N-terminus of preS1.⁶⁶² TLM might become functional following cleavage of envelope proteins on virus particles by one or several proteases present in endosomes. Curiously, the corresponding TLM motif in HBV is not required for infection,⁴⁴ suggesting that avian and mammalian hepadnaviruses might differ in their mechanisms of infection.

Several cellular and serum proteins that bind to HBV, DHBV, subviral HBsAg particles or recombinant envelope components have been identified since the mid-1980s as possible virus receptors.^{77,152,199,261,454,486,487,551,598,691,715,716,769} Many of these studies were of a descriptive nature and yielded only preliminary evidence of a role for the respective protein in viral entry. Exceptions are studies on a receptor candidate for DHBV, carboxypeptidase D (CPD). CPD was originally identified as a cell glycoprotein that binds DHBV particles and recombinant L protein.^{347,348} The DHBV-CPD interaction occurs in a species-specific manner, requires the PreS1-specific domain of the envelope protein, and is inhibited by PreS1 specific neutralizing antibodies.^{347,712} Many of the characteristics of CPD are consistent with its proposed role as a viral receptor. It is a type I transmembrane protein that cycles between the *trans*-Golgi network and the plasma membrane, and provides a high-affinity binding site for L within one of its three extracellular domains (domain C).^{63,650,734} This domain does not exhibit enzymatic activity. Both soluble CPD and antibodies against domain C can block infection of primary duck hepatocytes.^{733,734} Interestingly, CPD is downregulated in DHBV infected hepatocytes, which could contribute to the resistance of hepatocytes to superinfection.⁶² Such resistance could also be explained by other factors, including blocking of receptors by viral envelope proteins produced in the infected cell.⁷⁴⁵ However, while the evidence for a role of CPD in DHBV infections is compelling, proof for its role as a receptor is still lacking. The fact that CPD is expressed in cells that are nonpermissive for DHBV infections indicates that additional cell components must participate in the formation of a functional receptor complex and explains why transfection of cells with recombinant CPD does not confer susceptibility to DHBV infections, although particle internalization may occur.⁷¹¹ Glycine decarboxylase has been shown to bind truncated L protein and might represent a tissue-specific co-factor that plays a role for establishment of DHBV infections following the binding of virus particles to their cell-surface receptor(s).^{387,388} More recently, heparan sulfate proteoglycans have been invoked as low-affinity receptors for HBV that “capture” virus particles to facilitate binding to the high-

affinity, tissue-specific receptor(s).³⁷⁹ Moreover, evidence has been obtained for a role of caveolin-1 in entry of HBV in a tissue culture system.⁴²⁴ Finally, a recent report provided very strong evidence for a role of sodium taurocholate cotransporting polypeptide (NTCP, SCL10A1) as a receptor for HBV.^{777a}

After entry and uncoating of virus, capsids must be transported to the cell nucleus.³¹⁰ Experiments with capsids produced in hepatoma cells and in *Escherichia coli* provided evidence for a model in which core particles migrate along microtubules to the nuclear periphery. From there, capsids enter the nuclear basket in an importin α/β -dependent process and bind to nucleoporin 153.^{568,612} The model predicts that capsids disintegrate within the nuclear pore complex and release RC DNA into the nucleus,⁵⁶⁹ where it is converted into CCC DNA, the template for transcription of the viral RNAs.

Regulation of Transcription and Translation

Under physiologic conditions, CCC DNA is associated with histones and other proteins to form a mini-chromosome.^{51,52,488} Orthohepadnaviruses contain four promoters that control the transcription of the 3.5-kb preC and pgRNAs and the subgenomic 2.4-kb, 2.1-kb, and 0.8-kb RNAs, PreS1, S and X, respectively (Fig. 68.6). All promoters, except for preS1, lack a TATA box and hence produce transcripts with heterogeneous 5' ends, which in the case of the S and preC/C promoters encode distinct proteins: M and S, and pre-C and core/pol, respectively. The possibility that the PreC/C promoter actually consists of two distinct promoter elements has been suggested by genetic experiments and by naturally occurring mutants that fail to express HBeAg.^{76,205,508,603,798}

A single polyadenylation signal located in the core gene regulates the formation of the 3' ends of all four transcripts.⁶³⁹ In the case of Pre-C/C RNAs, RNA polymerase II bypasses the poly A signal once, leading to the formation of terminally redundant transcripts (Fig. 68.6). Sequences located close to the 5' end of the transcript play a role in the suppression of premature polyadenylation during the first passage by RNA polymerase II.⁵⁹⁷

The two enhancers, EN1, located upstream of the X region and EN2, overlapping the pre-C/C promoter, regulate the transcription of the four promoters.^{625,785} Consistent with the hepatotropic nature of hepadnaviruses, all transcriptional regulatory elements of HBV, except for the S promoter, contain binding sites for liver-enriched transcription factors (Fig. 68.7; for a more comprehensive description, see 341,604,624). For instance, the PreS1 promoter contains binding sites for the liver-enriched factors HNF1 and HNF3.^{134,240,413,573}

EN1, a highly complex enhancer less than 300 nucleotides in length, harbors binding sites for liver-enriched factors HNF1, HNF3, and C/EBP.^{108,514,719} In addition, the pre-C/C promoter and both enhancers contain binding sites for nuclear receptors (NRs) including HNF4 α , retinoid X receptor alpha (RXR α), peroxisome proliferator-activated receptor alpha (PPAR α), the chicken ovalbumin upstream promoter transcription factors (COUP-TF) 1 and 2, and others (reviewed in 341). Note that a clear separation between the binding sites on the pre-C/C promoter and En2 is not possible because of the overlap between the two elements. Ectopic expression of RXR α and PPAR α in NIH3T3 cells can induce the expression of pgRNA and the accumulation of HBV replication intermediates that otherwise are not produced in these cells, underscoring the significance of NRs in the control of viral gene expression.^{281,688,797} Curiously,

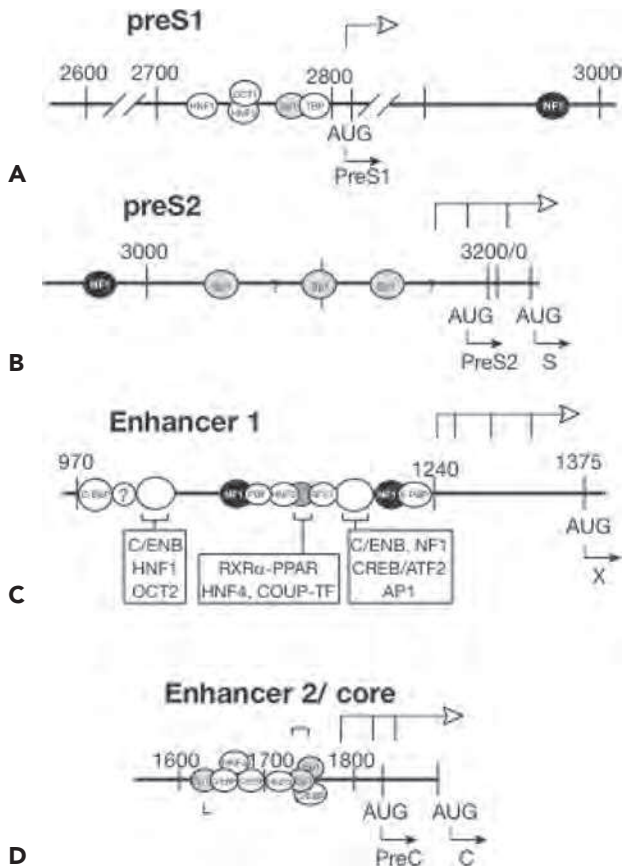

FIGURE 68.7. Transcription factor binding sites. The figure shows the binding sites for transcription factors on the preS1 and preS2 promoters (**A**, **B**), enhancer 1 and the X promoter (**C**) and enhancer 2 and the pre-core/core promoter (**D**) (adapted from [341]). Transcription start sites are indicated with arrows. For details see text. (**D** adapted from Kosovsky MJ, Qadry I, Siddiqui A. The regulation of hepatitis B virus gene expression: an overview of the *cis*- and *trans*-acting components. In: R. Koshy R, Caselman WH, eds. Hepatitis B virus: molecular mechanism in disease and novel strategies for antiviral therapy. London: Imperial College Press, 1998.)

substantial differences in the organization of the transcriptional control elements seem to exist among mammalian hepadnaviruses. For example, WHV does not bear an element corresponding to HBV enhancer EN1.¹⁵⁹

The exact mechanism by which these factors regulate transcription from CCC DNA is not well understood and major unresolved questions remain about the regulation of transcription from CCC DNA under physiologic conditions. For example, does transcription from all three major promoters occur simultaneously from the same copy of CCC DNA or does CCC DNA differentiate and support transcription from a subset of the four promoters? Because hepatocytes contain several copies of CCC DNA, it is possible that each CCC DNA undergoes a developmental process that leads to the inactivation of all but one promoter. Such a model would predict that the first CCC DNA molecule, derived from virion DNA, produces pgRNA, sufficient for initiation of viral DNA synthesis, and that CCC DNA derived from the intracellular CCC DNA amplification process (see Amplification and Stability of CCC DNA section) supports the transcription of either

pre-C, pg, X, or envelope mRNAs. For instance, COUP-TF1 was shown to suppress transcription of PreC/C transcripts in cell culture and might play such a role *in vivo*.⁷⁹⁷ Also, the viral core and X proteins could be involved in differentiation of CCC DNA. DHBV core proteins co-localize with pgRNA in infected hepatocytes and might play a role in the regulation of pgRNA synthesis.^{421,613} Moreover, HBx was shown to bind the HBV CCC DNA minichromosome and to act as a transactivator of the viral promoters.³⁶

Major mammalian and avian hepadnavirus transcripts are unspliced. In HBV and WHV, transport of unspliced viral RNA from the nucleus to the cytoplasm is regulated by a posttranscriptional *cis* regulatory element (PRE) on viral RNAs.^{164,165,283,288} PRE co-localizes with EN1 and a portion of the X gene. Avian hepadnaviruses appear to lack PRE. Instead, they contain positive and negative effectors of transcription (pet, net) that regulate the synthesis of pgRNA.²⁸⁴ Pet spans a 60-nucleotide-long sequence near the 5' end of pgRNA, whereas net is located downstream of the polyadenylation signal. Pet prevents net-induced termination of transcription of nascent pregenomes during the first passage of the RNA polymerase through the polyadenylation site. Like PRE, pet acts in an orientation-specific fashion, but its mode of action is unknown.

Evidence for the presence of a spliced transcript has been obtained with DHBV.⁵⁰² It contains a short sequence from the 5' end of pgRNA fused to PreS mRNA. The exact role of this transcript, if any, for viral replication is unclear. The observation of a spliced HBV transcript, this time encoding a fusion of S and pol, was made in chronically infected patients^{429,648,698} but, again, its functional significance is unknown.

Translation of HBV proteins is controlled by initiation codons located closest to the 5' end of the relevant mRNA. An exception is the polymerase protein. It is translated from an internal AUG codon on pgRNA located at the beginning of the *pol* gene (Fig. 68.6). Although many other viruses (i.e., picornaviruses, hepaciviruses) control internal initiation of translation with internal ribosome entry sites (IRES), hepadnaviruses do not have an IRES. Moreover, *pol* is not translated by a mechanism depending on a plus one frameshift from the core to the polymerase gene, as it has been described for certain retroviruses,²⁹⁵ since stop codons or frame shift mutations placed upstream of the initiation site have no effect on translation.^{95,608} One model, consistent with some experimental data, predicts that a small fraction of ribosomes recruited at the 5' end of pgRNA bypass the core AUG codon and scan the transcript until they reach the initiation AUG of the *pol* ORF.^{193,401} Another, more recent, model suggests that ribosomes bind at the 5' end but are then shunted to the initiation codon for *pol* without scanning the intervening codons.⁶²³ Whatever the correct mechanism, core and polymerase polypeptides accumulate at a constant ratio, which is believed to be in the order of 200 to 300 to 1.

Viral Proteins

CORE

The core protein of HBV is a 183- to 185-aa-long polypeptide of MW 21 kd with an arginine-rich "protamine" domain located at its C-terminus (residues 150–183) (Fig. 68.8). Avihepadnaviruses encode core proteins that are ~80 aa longer than HBV core, with similar properties except for an approximately 45-aa-long

FIGURE 68.8. Structures of the HBV capsid. The figure shows the dimeric structure of core proteins with Cys-61 (green) forming the disulfide bridge between the monomers and amino acid sequences of arginine-rich C-terminal domains of HBV and DHBV. The figure also shows the arrangement of the dimers in icosahedral capsids. (From Wynne SA, Crowther RA, Leslie AG. The crystal structure of the human hepatitis B virus capsid. *Mol Cell* 1999;3:771–780, with permission.)

insertion in the central domain of the polypeptide that forms the “spike” characteristic of viral capsids, and additional amino acids in the arginine-rich carboxy terminus.⁶⁵ CryoEM and X-ray crystallography helped reveal the structure of capsids produced in *Escherichia coli*.^{55,132,772} The folding of the core polypeptide chain is primarily α -helical and, unlike other viral capsid proteins, lacks β -sheets (Fig. 68.8). Two juxtaposed alpha helices ($\alpha 3$, $\alpha 4$) connected by a loop represent the central domain of the monomeric structure. Dimerization leads to the formation of a 4-helix bundle that assumes the shape of an inverted T, where the stem constitutes the dimer interface linked by a disulfide bridge and forms the spikes on the surface of capsids. The tips of the arms form the contact points, primarily located in $\alpha 5$, for the polymerization of the dimers into capsids. During an infection, the majority of capsids are assembled from 120 dimer subunits into a T = 4 structure. Capsids used for the structural studies were comprised of core proteins lacking about 30 aa from the C-terminus including serine phosphorylation sites and, as a consequence, exhibited an increased fraction of particles consisting of 90 dimers with T = 3. A structural analysis of the peptide that links the shell-forming core domain with the C-terminal region was consistent with a model predicting that the C-terminal “pro-tamine” domain provides a mobile platform for viral DNA synthesis inside capsids.⁷⁵⁷ Nevertheless, a conformational change at the exterior surface of capsids could still occur as a result of DNA replication in the interior, and provide a signal for the assembly of cores with envelope components, a step known to depend on DNA synthesis.^{534,671}

The C-terminal domain (CTD) contains three serine phosphorylation sites that are located at the beginning of arginine-rich motifs harboring nuclear localization signals.^{172,311,355,386,392,786} One or several cellular enzymes must mediate the phosphorylation because none of the viral proteins exhibit kinase activity. In cellular extracts the SR protein-specific kinases 1 and 2 (SRPK1, SRPK2) associate with cores and phosphorylate the three serine residues in the SPRRR motif.¹⁵¹

In addition, several kinases, including cyclin-dependent kinase 2 (Cdc2), protein kinase C, and a 46-kd serine kinase can phosphorylate cores *in vitro*.^{213,312,319} However, which kinases play a role in the HBV life cycle is still unknown. Moreover, it is not certain which kinase represents the protein kinase activity associated with Dane particles, which was first described more than 30 years ago.⁷ Experiments with DHBV revealed that DNA replication is accompanied by the gradual dephosphorylation in the core protein, which might contribute to a reorganization of the C-terminus.^{29,535,561,794,795} As with DHBV, all steps of HBV DNA synthesis may be regulated by serine phosphorylation in the core protein, indicating that this mechanism is shared by all members of the *Hepadnaviridae*.^{355,385,456} Finally, genetic studies demonstrated that the arginine clusters in the SPRRR motifs play a role in packaging of pregenomic RNA, and in DNA replication and perhaps in the recruitment of SRPK1 and SRPK2.³⁸⁵ Although the exact role of the charged arginine residues in DNA replication is not known, they might play a role in regulating the spatial organization of pregenomic RNA and minus-strand DNA to facilitate viral DNA synthesis.³⁷⁰

As mentioned previously, a second product derived from the core region is pre-core or HBeAg. It is translated from pre-C mRNA with 5' ends located a few nucleotides upstream of the first AUG in the pre-C/core open reading frame (Fig. 68.6). A signal sequence directs the translation of HBeAg to ER membranes. As a consequence, the protein enters the secretory pathway, where it undergoes a second cleavage event that removes about 34 aa from its C-terminus, before it is secreted from infected cells as a 15-kd protein.^{74,210,316,518,520,655,806} Expression of pre-core is not required for the establishment of productive infections in experimentally infected woodchucks and ducks.^{92,107} Consistent with these observations, HBV mutants that are defective for HBeAg production have been detected in patients with chronic infections.⁶⁸ One possible role for this protein could be to transiently suppress the immune response to the virus, thereby increasing

FIGURE 68.9. Proposed membrane topology of HBV envelope proteins. The orientation of the transmembrane domains (TM) is identical in S and M and the refolded L proteins. The external hydrophilic domain of S between amino acids 99 and 168 is illustrated at the left, along with the “a” determinant and the glycosylation site (*branched structure*) at asparagine 146. All proteins share a hydrophobic C-terminal domain that is embedded in membranes. M bears a second glycosylation site at its N-terminal extension (*thin line*). In the primary product of L, TM I is located in the cytosol where the N terminus is attached to membranes by the modification with myristic acid (for details see text). (Adapted from Bruss V. Envelopment of the hepatitis B virus nucleocapsid. *Virus Res* 2004;106:199–209.)

the frequency of chronic infections, which might explain the conservation of this gene. It is assumed that this function is no longer required once a chronic infection is established.¹⁰⁸

ENVELOPE

The three envelope proteins, L, M and S, encoded by the mammalian hepadnaviruses have two principal functions: (a) they provide the protein components of the virus envelope and (b) they assemble into aggregates that are secreted as subviral particles. L and M differ from S in their N-terminal regions (Figs. 68.6 and 68.9). As a consequence of the common S region, the three proteins share several features: they contain two topogenic signal I and II that determine their orientation in lipid bilayers, a hydrophobic C-terminal region that is most likely embedded in ER membranes and a common N-glycosylation site (Asn-146) in S. Like a conventional signal sequence, signal I is located at the N-terminus of S, but is not proteolytically processed. Signal II is a hydrophobic domain acting as a stop-transfer sequence and a signal sequence. As a result, the two hydrophobic domains form a hairpin structure with a cytosolic loop.^{170,171} The presence of a third hydrophobic domain invokes the theoretical possibility of two additional transmembrane passages. In addition to the common glycosylation site located downstream from signal II, the M protein harbors a second N-glycosylation site (Asn-4) near its N-terminus.²⁵⁸ This site is also present in L, but not used, because of the cytoplasmic location of the preS2 domain of L. Some HBV genotypes contain O-glycans (Thr-37) in the preS2 domain of both L and M proteins.⁶¹¹ L and M proteins contain modified N-termini. L carries a myristate group at Gly-2,⁵³⁹ whereas M is N-terminally acetylated.⁶¹⁰ The role of M in HBV replication is not yet understood, because this protein is not required for the production of Dane particles.¹⁸⁵ In avihepadnaviruses, L-proteins are also myristoylated, but not glycosylated.⁵⁶³ Instead they become phosphorylated in the preS1 domain.²²³

A major feature of L is that it exists in two conformations that differ in the localization of the N-terminal domain

(Fig. 68.9). In the first, the N-terminus, including signal I, is located in the cytosol,^{75,516,556} where it is required for binding of capsids and for the assembly of virions. In the second, the N-terminus is present in the ER lumen and, as a consequence, exposed on the surface of viral particles where it plays a role in the infection of hepatocytes.⁵⁵⁶ The conformational change is facilitated by interactions of L with the molecular chaperones Hsc70/Hsp40 and BiP.³⁵³ However, the details of the mechanism regulating this step are not yet understood. The major determinants for infectivity of HBV are located in the N-terminal 55 amino acids of L (44, 371, reviewed in 218). Evidence for this conclusion is derived from genetic experiments with mutant envelope proteins. In addition, peptides spanning different regions of the envelope proteins have been useful in mapping domains critical for infection. Experiments with peptides demonstrated the importance of N-terminal myristoylation. Myristoylated peptides are much more potent inhibitors of HBV infection than peptides with normal N-termini.^{23,219,224,542} A second region overlapping with the so-called “a” determinant or antigenic loop located between transmembrane domain II and the hydrophobic C-terminus of S contains a second infectivity determinant.^{367,600} However, the function of this determinant in infection is not yet known.

Following integration into membranes, envelope proteins form intermediates that include homo- and heterodimers stabilized by covalent disulfide bridges between different cysteine residues in the S domain, and subsequently assemble into either subviral or Dane particles^{290,637} (Fig. 68.5). S and M proteins contain the necessary signals for the export process because they can be secreted independently. In contrast, when synthesized in the absence of the other two envelope proteins, L is retained in membranes, suggesting that it carries a retention signal that prevents, in the absence of S and M, the export process controlled by its S domain.^{113,538}

In addition to their roles as envelope proteins, L and M can activate, *in trans*, the transcription from selected promoters in transfected cells.^{88,322} This function was initially described

for naturally occurring mutants of these proteins with C terminal truncations. Because truncated forms of L and M were initially identified in tissues from chronically infected patients, it has been speculated that they contribute to the development of hepatocellular carcinoma (HCC). Later work showed that the complete L protein could also transactivate selected promoters.^{190,262,263} This may be indirectly related to the fact that accumulation of L protein in the ER can lead to ER stress and consequently increase expression of M and S.^{287,773} This presumably facilitates L secretion and relieves ER stress. Thus, the transactivating potential of the HBV envelope proteins may ultimately reflect adaptations to facilitate survival of infected hepatocytes and might, but only in the long term, lead to transformation of rare infected hepatocytes.³⁵²

REVERSE TRANSCRIPTASE

Hepadnaviral polymerases have an approximate MW of 90 kd and consist of three functional domains: the terminal protein (TP) required for the priming of minus-strand DNA synthesis, and the reverse transcriptase (RT) and RNaseH for DNA synthesis and degradation of pgRNA. A spacer (hinge) separates the TP from the other two domains (Fig. 68.10). The spacer region appears to have no other function than to provide a flexible connection between the TP and RT domains.^{27,94} As will be discussed later in this chapter, RT is the target for all currently approved antiviral therapies with the exception of interferon.

Unlike retroviral RT, hepadnaviral polymerases are strictly template specific, which is a direct consequence of the mechanism for the activation of the enzyme. It requires binding of the polypeptide to the packaging signal, termed epsilon, located at the 5' end of pgRNA (a second copy of epsilon is located near the 3' end, but does not serve as a binding site for Pol; Fig. 68.11B). As is discussed later in this chapter, binding of the polymerase to epsilon leads to the priming of reverse transcription from a tyrosine residue (Y65) in the TP domain.^{362,747,758} This results in the formation of a covalent link between the polymerase and the nascent viral minus strand. However, this priming activity of Pol also requires cellular factors, explaining why early attempts to demonstrate polymerase activity with Pol expressed in bacteria were not successful, although similar strategies yield functional retroviral polymerases.⁶⁸⁶ Enzymatically active polymerase was first produced with the DHBV enzyme translated in rabbit reticulocyte lysates, and led to the discovery that the interaction between the polymerase and epsilon RNA is dependent on chaperones including heat shock proteins 90 (Hsp90), Hsp70, and p23.^{276,278,654} Consistent with these observations, both DHBV and HBV replication are sensitive to geldanamycin and its derivatives, which bind to the N-terminal ATP binding domain of Hsp90.^{275,278} Similarly, novobiocin, which binds to the C-terminus of Hsp90, inhibits HBV replication.²⁷⁵ Moreover, Hsp90, p23, and three additional chaperones—Hsp70, Hsp40, and Hop—can activate DHBV

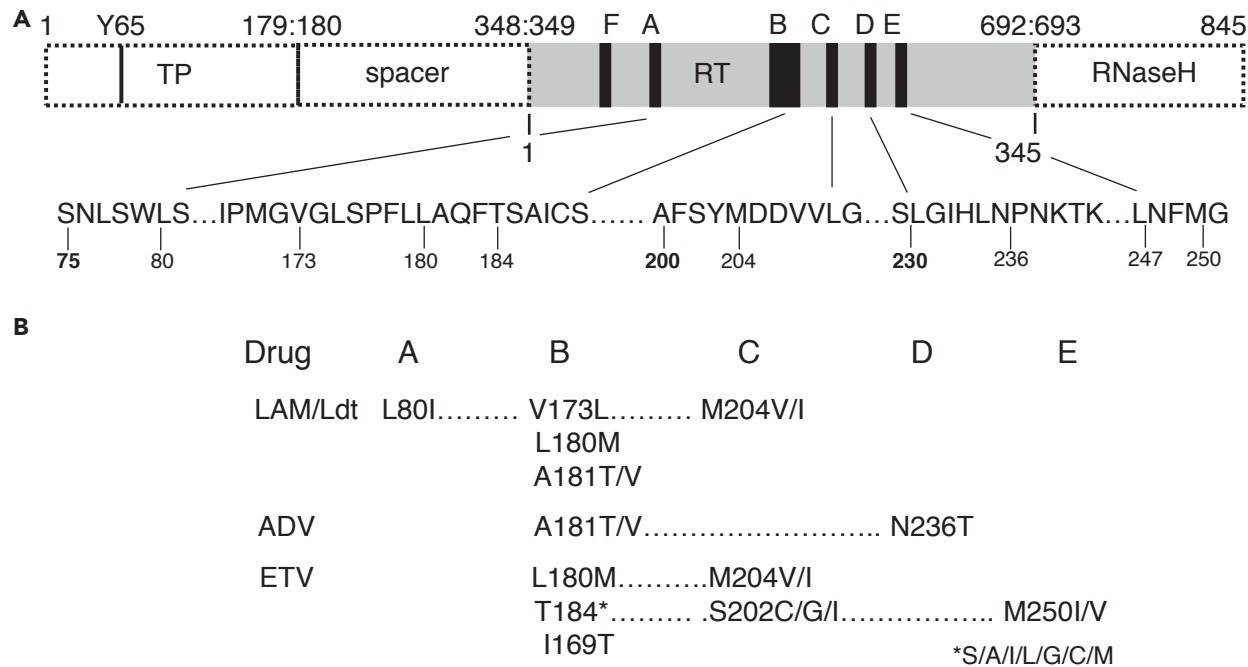

FIGURE 68.10. Physical organization of the HBV polymerase and resistance to nucleoside analogs. A: Domains of the pol protein. The polymerase contains three main functional domains, the terminal protein domain (TP), the reverse transcriptase (RT) domain, and the RNaseH domain (A). Functional domains within the RT have been assigned based on structural modeling using the crystal structure of the HIV RT as a guide.^{150a} By this analogy, domains A, C and D would appear to be involved in deoxynucleotide binding and polymerization. The B domain is thought to participate in template binding and the E domain in binding of the primer strand. **B:** Resistance mutations. The figure shows the location of amino acid mutations that confer resistance to lamivudine (LAM) and telbivudine (Ldt), adefovir (ADV) and entecavir (ETC). (Adapted from Zoulim F, Locarnini S. Hepatitis B virus resistance to nucleos(t)ide analogues. *Gastroenterology* 2009;137:1593–1608.)

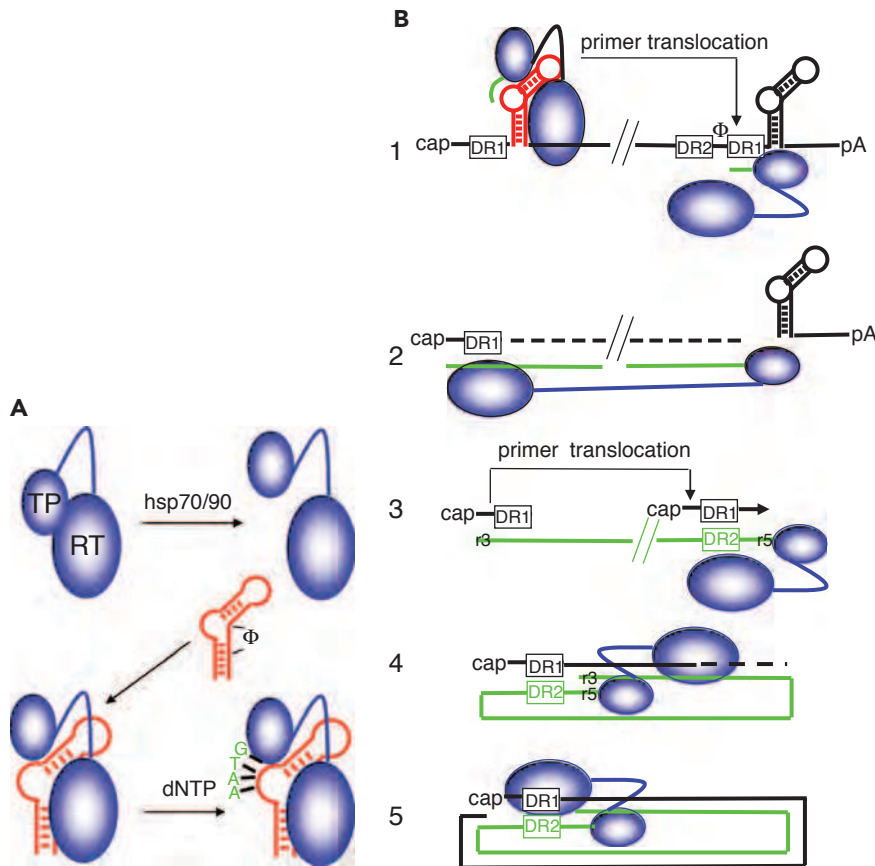

FIGURE 68.11. Genome replication. A: Binding of epsilon RNA to the TP and RT domains of the polymerase facilitated by chaperones (hsp70/90) and initiation of reverse transcription at the bulge of epsilon RNA as described in the text. Phi (Φ) depicts the RNA sequence on epsilon proposed to be required for circularization of pgRNA (see **B**). **B:** The figure depicts five important steps in viral DNA synthesis: 1) Transfer of the DNA primer from epsilon to DR1 near the 3' end of pgRNA; 2) Elongation of minus-strand DNA and digestion of pgRNA by RNaseH of the polymerase; 3) Transfer of the capped RNA primer from DR1 to DR2 and synthesis of plus-strand DNA to the 5' end of minus-strand DNA; 4) Template switch of the nascent plus strand with the help of the small terminal redundancies r5 and r3, resulting in circularization of the genome; 5) Completion of plus-strand DNA as described in the text. The figure was not drawn to scale.

and HBV polymerases to bind to epsilon RNA *in vitro* and, in the case of the DHBV polymerase, restore the protein-priming activity.^{275,277} With HBV, the protein-priming activity has been demonstrated in insect cells,³⁶¹ but so far not in bacteria or the reticulocyte lysate system. With DHBV enzymatically active polymerase can also be expressed in yeast.⁶⁹⁰

The function of the chaperones is not completely understood, because structural information about the polymerases of hepadnaviruses is lacking. It is possible that they stabilize an energetically unfavorable conformation of the polymerase and, in this way, facilitate the binding of polymerase with epsilon RNA^{84,653} (Fig. 68.11A). Consistent with such a model is the observation that DHBV polymerases with deletions of the RNaseH domain can exhibit protein-priming activities in the absence of cellular factors.⁷⁵⁰ Thus, these domains might hold the polymerase in a “closed” conformation that, in the absence of chaperones, prevents interaction with the packaging signal.

It is likely that a single polymerase polypeptide catalyzes one complete round of DNA replication because assembly of the polymerase into capsids depends on its interaction with epsilon sequences on pgRNA, which would indicate that polymerase and RNA templates are present at equimolar amounts in subviral particles.^{25,803} Consistent with such a model, experiments meant to quantify polymerase levels in HBV capsids revealed a molar ratio of ~0.7 polymerase molecules per virion DNA.^{25,26}

HBx

X is an enigmatic protein of the orthohepadnaviruses that is required for efficient infection and replication *in vivo*.^{106,415,804,814}

Expression of this polypeptide has been assessed in the livers and primary hepatocytes from WHV-infected woodchucks where it can accumulate to 40,000 to 80,000 copies per cell in the cytoplasm.¹⁴⁸ In contrast, in hepatoma cell lines HBx can be detected in both the cytoplasm and the nucleus.¹⁶⁶ However, the exact role of X activity has been difficult to elucidate because the protein interacts with many cellular factors, including the proteasome, and its activity varies depending on the cell lines used for a study (for more detailed reviews see 57, 475).

Originally, HBx was identified as a relatively weak transactivator for promoters with NF- κ B, AP-1, AP-2, c/EBP, ATF/CREB, or NFAT binding sites in tissue culture cells. Because HBx does not bind directly to DNA, it regulates transcription either directly by binding to transcription factors and chromatin (e.g., on CCC DNA), or indirectly through activation of signal transduction pathways in the cytoplasm (Fig. 68.12).^{36,57,594,649,726} For example, it has been reported that HBx enhances the binding affinity of CREB, a member of the basic leucine zipper family, for the CREB/ATF2 binding site in HBV enhancer I (Fig. 68.7).^{427,765} Other reports provided evidence for binding of HBx to p53,⁷⁵¹ the RNA polymerase subunit RPB5⁶⁸¹ and the DNA helicase components, ERCC2 and ERCC3 of TFIIH.⁷⁵¹ Whether *in vivo* HBx is essential for transcription of viral RNAs or regulation of cellular genes required for the viral life cycle is difficult to assess. Experiments with hydrodynamically injected mice demonstrated that nuclear (but not cytoplasmic) HBx acts as a transactivator of the viral promoters and, by inference, might exert this activity in the natural life cycle of the virus.^{320,321}

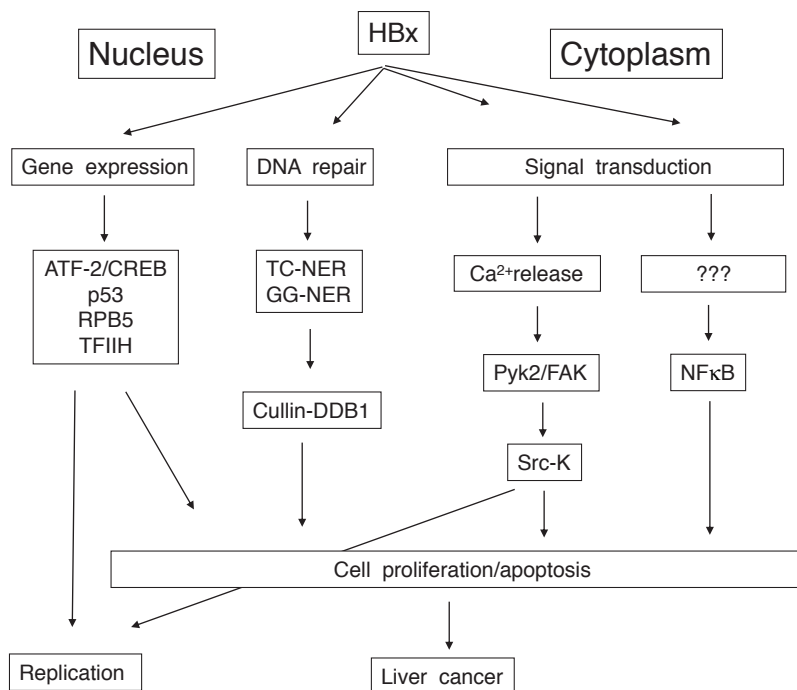

FIGURE 68.12. Model for HBx functions. The figure depicts three major proposed activities of HBx: regulation of gene expression, inhibition of DNA repair and activation of several signal transduction pathways described in the text.

Investigations on the cytoplasmic activity of HBx led to a model predicting that expression of HBx induces the release of calcium ions (Ca^{2+}) into the cytosol, either from the ER or from mitochondria.⁵⁸ The transient influx of Ca^{2+} then activates the nonreceptor tyrosine kinases proline-rich tyrosine kinase 2 (Pyk2) and focal adhesion kinase (FAK), which in turn activate the Src family kinases (Src-K) (Fig. 68.12). The latter are known to activate the downstream Ras-Raf-MAP kinase signal transduction pathways. In HepG2 cells, where X expression can significantly stimulate viral DNA synthesis, drugs that chelate intracellular Ca^{2+} or prevent activation of Src-K can inhibit HBV replication.⁵⁶ Conversely, compounds known to induce the efflux of Ca^{2+} into the cytosol can increase the replication levels of HBx negative mutants. Nevertheless, it needs to be determined whether expression of HBx in natural infections triggers the transient Ca^{2+} fluxes that have been observed in transfected hepatoma cell lines, and how this activity is involved in chronic infection of liver cells *in vivo*. Notably, the effects on viral replication appear to be independent of the Ras pathway, suggesting that Ras-dependent activation of transcription is not required. One possibility is that X-activated pathways play a direct role in viral replication by regulating the phosphorylation of the viral core protein.⁴⁵⁶ While a model invoking a role for HBx in the release of Ca^{2+} is consistent with many activities attributed to this polypeptide, including activation of transcription, cell-cycle control, and apoptosis, it cannot explain all the features of the protein, most notably, the reported activation of NF- κ B.^{116,383,416,666}

Several groups reported that expression of X proteins from both HBV and WHV can inhibit nucleotide excision repair (NER) through binding to DNA damage-binding protein 1 (DDB1),^{35,301,375,642} though it remains unclear if inhibition is specific to global or transcription-coupled NER, or to both. More recent studies provided evidence for an HBx-DDB1 complex binding to cullin4A-RING (CUL4A) ubiquitin ligase. This association is mediated by DDB1 acting as

an adaptor protein.⁵⁴⁴ Structural data has revealed an α -helical motif at position 88 to 100 in HBx that binds to the BPA-BPC domains of DDB1,³⁹⁰ and validated the HBx-CUL4A interaction.³⁹¹ Thus, HBx might act as a bridge linking the CUL4A-DDB1 complex to a substrate that is then ubiquitinated by the CUL4A-RING ubiquitin ligase. The substrate for the CUL4A-DDB1-HBx complex is not known. Notably, the V proteins of simian virus 5 and human parainfluenzavirus type 2 can redirect the CUL4A-DDB1 ligase to STAT proteins, promoting polyubiquitination and degradation of these transcription factors.^{160,729} Hence, it is possible that HBx plays a role in inhibiting innate immune pathways. Results from recent work indicated that HBx can inhibit dsDNA-induced activation of the RIG-I pathway.⁷⁸⁶ Alternatively, the protein might play a role in regulating a cellular pathway required for a specific step in viral life cycle, such as the formation of CCC DNA. In addition to its role in HBV replication, HBx might also play a role in the development of liver cancer, as discussed later in this chapter.

Identification of the physiologic role of HBx in viral replication and pathogenesis remains one of the most challenging problems in HBV biology. The lack of mouse models or hepatocyte cell lines permissive for HBV infections has stymied efforts to investigate relevant HBx-dependent host-virus interactions that play a role in viral replication during natural infections. Nevertheless, many important properties of HBx have been uncovered with available experimental systems. It is certain that HBx is required for viral replication *in vivo* and that HBx expression may effect signal transduction and other gene expression pathways that alter the physiology of hepatocytes in a fashion that promotes viral replication and persistence. The use of primary hepatocyte cultures in lieu of immortalized or transformed cell lines might be required to unravel the true function of HBx. For example, recent studies with primary cultures provided evidence for a role of HBx in promoting progression of the cell cycle from G0 to G1.³⁸⁶

Replication of Genomic Nucleic Acid

FORMATION OF CCC DNA

The first step in the hepadnavirus replication cycle is the conversion of genomic RC DNA into CCC DNA (Fig. 68.5). Although the details of the mechanisms responsible for this step are not understood, a comparison of the two DNA forms can be used to establish a model for CCC DNA formation. It predicts that the polymerase and one of the terminally redundant segments on the minus strand, termed *r*, are removed prior to the ligation of the two ends. Similarly, a capped RNA oligomer present at the 5' end of plus-strand DNA must be removed and the incomplete plus strands extended before the ends can be joined. Whether the viral DNA polymerase or a cellular polymerase elongates the 3' end of plus strands is not known. Reverse genetic experiments with DHBV suggested that an endonuclease removes the 5' end of minus strand DNA prior to CCC DNA formation, leading to the formation of a protein-free RC DNA, which can be detected in tissue culture cells.^{209,235,330,647} Most likely, cellular DNA repair enzymes are responsible for the conversion of RC to CCC DNA. Consistent with this view, CCC DNA formation following infection of primary hepatocyte cultures with DHBV or WHV is not blocked by inhibitors of the viral polymerase.^{198,470} Whatever the exact mechanism of CCC DNA synthesis, it must be extremely efficient, because in natural infections virions have a specific infectivity close to one.^{16,305}

PACKAGING OF pgRNA

pgRNA (C mRNA) has dual functions in viral replication. It acts both as the mRNA for the translation of the core and polymerase polypeptides and as the template for genome replication. The transition from the first to the second function is triggered by the binding of the polymerase to the packaging signal, epsilon, at the 5' end of the mRNA (Fig. 68.11A). In turn, this reaction creates a signal for the assembly of this ribonucleoprotein complex (RNP) into capsids. Polymerases preferentially bind to their own mRNA, possibly while translation is still ongoing, which increases the chance for packaging and replication of biologically intact pgRNA.^{26,265,285} The interaction between the polymerase and epsilon RNA requires cellular chaperones, as described earlier. While structurally intact polymerase is required for RNA packaging, DNA polymerization activity *per se* is not required for this process, indicating that the RNP can induce assembly without a requirement for DNA synthesis.^{24,94,111,265,596} Nevertheless, as will be discussed, packaging and initiation of reverse transcription are intimately linked events.

Based on secondary structure predictions, epsilon contains two inverted repeats that can fold into an RNA hairpin with a basal and apical stem that are separated by a bulge (Fig. 68.11). The upper stem is capped by a loop.^{33,189,279,307} RNA footprint analysis of free and bound epsilon RNA suggested that binding of the polymerase could induce a single-stranded conformation in the upper stem.³⁴ Again, it should be noted that due to a terminal redundancy (*R*), epsilon RNA is present at both ends of pgRNA. However, genetic experiments showed that only the 5' copy provides a binding site for the polymerase and is required for packaging.^{307,327,546} Consistent with these results, evidence has been obtained that the nearby cap structure on pgRNA may play a role in RNA packaging. These results also evoked the possibility that the polymerase might interact with translation factors to induce a transition from translation to replication.³⁰⁰

Interestingly, epsilon maps upstream of the AUG for core, and evidence has been obtained that translation of pre-C RNA, with passage of 80S ribosomes through epsilon, prevents its packaging.⁴⁸³

In contrast to the mammalian hepadnaviruses, packaging in the avian viruses requires, in addition to epsilon, a second pregenome sequence, termed region II, located about 900 nucleotides downstream of epsilon and spanning approximately 300 nucleotides.^{83,266,517} The role of this downstream sequence in RNA packaging is not yet understood.

In addition to the chaperones required for RNA packaging described previously, the human cytidine deaminase APOBEC3G is incorporated into viral particles through binding to the viral reverse transcriptase.^{490,491} Ectopic expression of several members of the APOBEC family of proteins inhibits HBV replication.⁵⁹² Notably, unlike the inhibition by APOBEC of retrovirus and retroposon replication,⁵⁹³ inhibition of HBV was not dependent on the catalytic activity of the deaminase. Instead, it appears that the protein inhibits virus replication during an early step of minus-strand DNA synthesis, perhaps by binding to viral RNA or the polymerase.⁴⁹⁰

MINUS-STRAND DNA SYNTHESIS

The first step in minus-strand DNA synthesis is the priming reaction that leads to the formation of a covalent link between a tyrosine residue in the TP domain of the polymerase and dGMP (Fig. 68.11A).^{359,747,758,813} The template for this protein-priming reaction is a C residue located in the bulge of epsilon. Although *in vitro* priming can occur immediately following the binding of the RT to epsilon in the absence of core protein, the exact sequence of events in infected cells is not known. Thus, priming could occur prior to, during, or after the assembly of capsids. To complete the priming reaction the polymerase copies the next two or three nucleotides from the bulge of epsilon. As a consequence of this mechanism, the polymerase remains covalently linked to the 5' end of minus-strand DNA during all subsequent steps of viral DNA synthesis, virus assembly, and release.^{214,468,469}

To continue DNA synthesis, the 3- to 4-nt DNA oligomer is transferred to the 3' end of pgRNA, where it anneals with a complementary sequence motif located in a 10- to 12-nucleotide-long region known as DR1 (Fig. 68.11B, step 1).⁷⁴⁶ However, the 3- to 4-nucleotide acceptor site by itself is too short to specify the transfer to DR1. Additional sequences on pgRNA are necessary to control the translocation of the DNA primer to DR1. The selection of the natural site is most likely facilitated by the structural arrangement of pgRNA in the capsid. The acceptor site and epsilon RNA must be held in close physical proximity to facilitate the transfer of the 3- to 4-nt oligomer across the pregenome. Indeed, a short *cis*-acting element, termed phi (Fig. 68.11A), located upstream of the acceptor site at DR1 is required for accurate minus-strand DNA synthesis from DR1 in HBV, but not DHBV.^{2,431,633,687} Phi can base-pair with the 5' region of epsilon RNA, thereby stabilizing the predicted structural conformation of pgRNA required for the transfer of the short minus strand. Following the translocation reaction, minus-strand DNA synthesis continues all the way to the 5' end of the RNA template (step 2). During this reaction, pgRNA is degraded by the RNaseH activity present near the C-terminus of the polymerase.^{110,570,671} Due to the location of DR1 within the terminal redundancy

on the pregenome, the completed minus-strand DNA bears the short terminal redundancy, *r*. As described below, *r* plays a role in the circularization of the viral genome.^{400,617,764}

PLUS-STRAND DNA SYNTHESIS

Plus-strand DNA is primed by an 18-nucleotide-long, capped RNA oligomer derived from the 5' end of pgRNA. The oligomer contains a complete copy of DR1 and represents a product of the RNaseH activity of the polymerase (Fig. 68.11B, step 3).^{399,410} As a consequence of this priming mechanism, plus-strand DNA synthesis can only begin after minus-strand DNA synthesis is complete. To prime plus-strand DNA synthesis, the RNA oligomer must first translocate to and anneal with DR2, located near the 5' end of the minus-strand DNA and identical in sequence to DR1.^{399,617,657,764} As expected, mutations that disrupt the homology between DR1 and DR2 block the formation of RC DNA and instead favor an *in situ* DNA priming reaction from the nontranslocated primer, leading to the formation of double-stranded linear (dsl) DNA.^{130,657,783} DSL DNA is produced even under natural conditions, albeit with a low frequency of about 5% to 20% of RC DNA (Fig. 68.5).

The mechanism responsible for the transfer of the RNA primer to DR2 is not completely understood. The most likely scenario is that the regions encompassing DR1 and DR2 on minus-strand DNA are juxtaposed to facilitate the transfer of the primer from DR1 to DR2. Studies with DHBV and HBV revealed the presence of three sequence motifs on the minus strands, which have the potential to form short duplexes that might stabilize a secondary structure required for plus-strand primer translocation.^{241,256,384,408,473} Mutations that would be expected to disrupt the formation of these duplexes inhibited RC DNA, but not dsl DNA synthesis.^{384,407,408} In addition, capsid proteins might impose certain structural constraints on minus strands and thereby play a role in primer transfer.

Following the priming reaction at DR2, plus-strand DNA synthesis ensues until it reaches the 5' end of minus-strand DNA. At this point, a template switch (i.e., circularization) is required for the continuation of DNA synthesis (Fig. 68.11B, step 4). The template switch is facilitated by the aforementioned terminally redundant sequences, *r*, in minus-strand DNA. The structural requirements for this reaction must be complicated, because the polymerase attached to the 5' end of the minus strand accommodates both ends of the minus-strand DNA in close proximity. In spite of the expected steric constraints, the polymerase can copy the entire *r*5 region, including the dGMP residue that is covalently linked to the RT, and then induce the necessary template switch to *r*3.⁴⁰⁹ As with priming at DR2, this recombination event also depends on the formation of small duplexes on distant sites in minus-strand DNA, indicating that the two critical steps in plus-strand DNA synthesis might be controlled by the same mechanism.^{255,472}

In mammalian hepadnaviruses, plus-strand DNA synthesis is incomplete and reaches approximately half the genome length prior to virion formation.^{585,671} The cause and significance of the premature termination of plus-strand synthesis remains obscure. Perhaps the arrest in DNA synthesis is caused by steric factors imposed by the capsid and by the polymerase itself. For instance, capsids of HBV assembled from core proteins with truncated C-termini accumulate virion DNA with a greater deficiency in plus-strand synthesis, and a shift to *in situ* priming of plus-strand elongation⁴⁸²; with DHBV, capsids assembled

with core proteins with truncated C-termini are also defective in plus-strand elongation.⁷⁹⁴ Thus, capsid structure can influence elongation of plus-strand DNA. In addition, the coating of capsids with envelope proteins probably leads to the depletion of the dNTP pool prior to the completion of DNA synthesis. This latter possibility is supported by the fact that plus-strand DNA can be extended in an *in vitro* reaction in the presence of precursor dNTPs and nonionic detergents that disrupt the viral envelope^{314,671} (Fig. 68.2). In contrast to orthohepadnaviruses, plus-strand DNA synthesis in wild-type avihepadnaviruses is virtually complete,⁴⁰⁰ except that the polymerase does not displace the RNA primer from DR2, so DR2 has to be copied prior to CCC DNA formation.

AMPLIFICATION AND STABILITY OF CCC DNA

The fate of DNA-containing capsids in the cytoplasm of infected cells is twofold: The particles either enter the cell nucleus and release RC DNA or assemble with envelope proteins into virions and enter the secretory pathway (Fig. 68.5). The first pathway amplifies the copy number of CCC DNA.^{724,770} Using DHBV, CCC DNA amplification in cultures of nondividing hepatocytes was shown to occur early in an infection when the cytoplasmic concentration of viral envelope proteins is still low.^{675,676} The final, average CCC DNA copy number per nucleus *in vivo* is usually between 1 and 50.^{306,308,466,802} The route and mechanism of transport of capsids to the nucleus are unknown. Transport of newly made capsids from the cytoplasm to the nucleus does not require envelope proteins because CCC DNA amplification occurs when hepatocytes are infected with viral mutants that are unable to synthesize these proteins.^{675,676} Instead, signals generated on capsids during their maturation might play a role in retrograde transport.

A critical issue with important implications for antiviral therapies with inhibitors of viral DNA replication is whether CCC DNA has a half-life and, therefore, whether ongoing CCC DNA synthesis is required to maintain a steady state within a nondividing cell. An early study¹²⁶ addressed CCC DNA stability with a BUDR pulse/chase protocol using primary, nondividing cultures of hepatocytes derived from ducks infected with DHBV. CCC DNA labeled in a pulse chase appeared completely stable. However, if BUDR was instead added later and the fate of unlabeled CCC DNA present prior to BUDR addition was followed, a shorter half-life of 3 to 5 days was observed. This discrepancy is not yet understood. In another study, CCC DNA stability in the presence of reverse transcription inhibitors was analyzed following infection of primary woodchuck hepatocyte cultures with WHV. These experiments suggested a half-life greater than 30 days in nondividing hepatocytes.^{470,809} CCC DNA also appeared to survive mitosis in primary woodchuck hepatocyte cultures that were treated with adefovir dipivoxil to block viral DNA synthesis.¹⁴⁵ A fourth study took a different approach, examining CCC DNA stability in chicken hepatoma cells expressing DHBV from an inducible promoter.²³⁸ This study, like the earlier study in duck hepatocytes, reported a short CCC DNA half-life: ~2 days. Moreover, it suggested that CCC DNA could survive cell division and partition to daughter cells and thus, that in the absence of new viral DNA synthesis, CCC DNA would be gradually lost from cells through dilution, as also demonstrated in a chimeric mouse model with implanted human hepatocytes.⁴¹⁹ A fifth study demonstrated a CCC DNA half-life of ~14 days in HepG2 cells transduced with HBV using

a baculovirus vector.¹ Given the possibility that cell loss might have contributed to CCC DNA loss in the LMH and HepG2 cell-line experiments, published studies seem to suggest, on balance, that CCC DNA is stable in nondividing cells in culture, and perhaps in dividing cultures as well.^{145,238} Some,^{5,418,809} but not all^{759,771} *in vivo* studies of antiviral therapy with nucleoside analogs that inhibit viral DNA synthesis suggest that CCC DNA may be stable in the chronically infected liver and survive through mitosis. The idea that CCC DNA stability is high is also supported by studies of competition in the fully infected liver between strains of DHBV with different replication rates. Competition between the strains essentially stops in the fully infected adult liver, where cell turnover is low, again suggesting that CCC DNA has a lower turnover rate in infected cells.⁸⁰¹

Virus Assembly and Release

Assembly of hepadnaviruses is still a poorly understood process. Assembly of Dane particles occurs in at least two distinct steps: the formation of capsids that contain pgRNA and RT and the formation of enveloped virus particles that contain the viral DNA genome. During DNA synthesis, capsids gain the ability to interact with envelope proteins.^{290,531} (Fig. 68.5). The N-terminal domain of L plays an important role in this interaction because M and S proteins alone cannot support translocation of capsids across membranes.³⁸¹ Recent reports provided evidence for a mechanism in which DNA containing core particles assemble with envelope proteins at membranes of multivesicular bodies (MVPs).^{323,754} This model is supported by data demonstrating a requirement for vacuolar protein sorting proteins AIP1 and VPS4B in assembly and release of virus (Dane) particles.⁷⁵⁴ In contrast, formation and secretion of SVPs occur through the ER-Golgi compartment and do not depend on MVPs. Other factors reported to interact with capsids and envelope protein that could play a role in assembly include the ubiquitin ligase Nedd4,⁵⁹⁵ gamma2-adaptin, a clathrin adaptor protein,²⁵⁴ and thioredoxin-related transmembrane protein 2,⁷⁰⁸ a protein involved in clathrin-mediated endocytosis and, hence, the early endocytic pathway. The observed interaction of capsids with Nedd4 is particularly interesting because members of the Nedd4 family of ubiquitin ligases play a role in linking capsid proteins of certain retroviruses and RNA viruses with components of the ESCRT (endocytic sorting complexes required for transport) machinery that sorts cargo proteins into the luminal vesicles of MVPs and facilitates budding.²⁰⁰

PATHOGENESIS, PATHOLOGY, AND EPIDEMIOLOGY

Entry into the Host

HBV is found at high titers, sometimes up to 10^{10} Dane particles per ml, in the blood of infected individuals. Thus, the main routes of infection involve exposure to blood or blood-derived products, such as during childbirth from an HBV-positive mother, blood transfusion, or other potential sources of percutaneous exposure, including sexual intercourse.³⁷⁷

Perinatal Infections

The greatest sources of infection worldwide are from infected mothers to newborns, or among very young children. The risk

of vertical transmission varies depending on geographic regions. In Asia, the rate of perinatal transmission from infected mothers is as high as 90%, because many of the pregnant women that are chronically infected have high titers of circulating HBV. In infants infected by HBV, the rate of chronicity reaches 90%⁶⁵⁹ without vaccination. In North America, Western Europe, and Africa, the risk of vertical transmission from chronically infected mothers is about 10% without any preventative therapy. This lower risk is consistent with reports that infected mothers in these locales usually have a low viral load. These different viral loads are likely a result of different natural histories of chronic infection in the different locales, with infections at the time of birth that become chronic, leading to a more persistent high-level viremia than infections later in life. That is, women infected at birth would have a higher viremia as they aged and would be more likely to pass the infections to the neonate than women infected later during the first few years of life. Thus, the high rate of chronicity in Africa appears mostly due to horizontal spread to young children from playmates and adults involved in their care, rather than directly from infected mothers during birth.

Additional Routes of Transmission: Blood Transfusion, Intravenous Drug Use, Sexual Transmission and Nosocomial Infections

The risk of HBV transmission by blood transfusion has decreased dramatically since the early 1970s because of the exclusion of paid donors and the introduction of serologic screening of volunteer blood donors for serum HBsAg and anti-HBc immunoglobulins. In the United States, the risk of HBV transmission via blood products is now one out of 63,000 transfusions, down from 15% in the 1960s.^{12,220} The current incidence may be attributed to the failure to identify infected blood donors because of the serologic window during the incubation period following infection, the presence of some rare HBsAg variants that are not detected by the serologic assay for HBsAg, particularly when concurrent testing for anti-HBc is not performed, and the problem of so-called occult HBV infections, in which neither HBsAg or anti-HBc are detected.

In contrast to blood transfusion, percutaneous infection of young people and adults via intravenous drug use, tattoos, acupuncture, ear piercing, sharing razors, and other avenues, remain as major modes of HBV transmission. Sexual transmission still represents 40% of the new cases of acute hepatitis B in many developed countries,^{12,220} while the role of intravenous drug use seems to be decreasing with time, currently representing 6% to 10% of new cases. HBV can also be transmitted by accidental needle stick in the healthcare setting.^{12,220} Nosocomial transmission represents approximately 10% of the new cases of HBV infection, usually as the consequence of invasive treatment or diagnostic procedures. The risk of accidental transmission by percutaneous route is estimated to be 30% from highly viremic patients. Transmission from healthcare worker to patients may also occur.²⁵³ Other cases of nosocomial transmission have been reported in hemodialysis centers, and in the setting of organ transplantation, even from donors who only have anti-HBc antibodies. When found alone, anti-HBc antibodies are usually a marker of a past infection from which an individual has recovered. HBV infection of the liver graft recipient, presumably virus reactivation in the donor liver, is observed in more than 50% of cases when the donor has

antibodies to HBcAg but no other serologic markers of HBV infection.¹⁵³ As will be discussed later, this is consistent with other studies indicating that residual amounts of HBV remain for years or decades after clearance of transient infections. Horizontal transmission can be observed among institutionalized persons via close bodily contact, leading to HBV infection through minor skin breaks and mucous membranes.⁷³⁷

In brief, high-risk groups for HBV infection include healthcare workers, especially surgeons and physicians working in hemodialysis, oncology, or AIDS units; laboratory workers in contact with blood or human fluids; institutionalized handicapped persons, their attendants, and family; patients requiring frequent blood product transfusions in countries where blood screening procedures are inadequate; patients on hemodialysis; patients with organ transplantation; intravenous drug users; men who have sex with men; and promiscuous heterosexuals.

The Liver and Its Response to HBV Infection

The main cellular target of HBV is the hepatocyte, which in humans is the only cell type convincingly shown to replicate the virus. However, the belief that other cells replicate the virus in humans has persisted, despite a lack of conclusive evidence.

The liver has a central role in synthesizing plasma proteins, storing and metabolizing glycogen as a source of energy, removing dead and dying cells from the blood stream, and detoxifying

harmful chemicals, among other things. Structurally, the liver is comprised of microscopic lobules into which blood enters from the hepatic artery and portal vein, which are situated in a region known as the portal triad, and exits via the hepatic vein. The lobule itself is not an anatomically defined structure but a region arbitrarily defined by the positioning of the portal tracts and central vein. The structure of a small portion of a lobule is illustrated in a two-dimensional view in Figure 68.13. The parenchymal cell of the lobule, comprising 60% to 70% of liver cell mass, is the hepatocyte. Other cells include bile ductule epithelial cells, sinusoidal endothelial cells, hepatic stellate cells (Ito cells), and Kupffer cells, the resident liver macrophages. In addition to the portal vein and the hepatic artery, the triad also contains lymphatics as well as the bile duct, through which bile, produced by hepatocytes during breakdown of bilirubin, is exported to the gall bladder and small intestine. In contrast to blood, which flows away from the portal tracts to the central vein, lymph⁵⁰⁷ and bile flow towards the tracts. Lymph flows through the space of Disse, between hepatocytes and the overlying endothelial cell layer, and bile is excreted into and flows via channels (canaliculi) formed at the interface of adjacent hepatocytes. Bile enters the bile ductules through a specialized structure known as the Canal of Hering. Destruction of large numbers of hepatocytes during immune clearance of hepatitis virus infections leads in some patients to jaundice (icterus) due

FIGURE 68.13. Structure of the liver lobule. Two-dimensional representation of a small portion of a liver lobule with various cell types present (hepatic stellate cells, localized between sinusoidal endothelial cells and hepatocytes, within the space of Disse, are not shown). Blood enters the lobule from the hepatic artery and portal vein, and flows through the sinusoids bounded by plates of hepatocytes, exiting at the central vein. Hepatocytes produce bile, which is released into bile canaliculi, small channels formed where the apical surfaces of hepatocytes make contact, flows to the canals of Hering and then to bile ductules. From there it flows to larger ducts and exits the liver. The origin of hepatic progenitor cells, which normally only appear during certain conditions of acute and chronic liver injury, is also illustrated. The exact location of progenitor cells in the healthy liver is uncertain, with different lines of evidence pointing to either bile duct epithelium or cells in the canals of Hering. In the actual lobule, many plates of hepatocytes connect the portal triad to the central vein, though only two are shown here.

to a buildup of bilirubin in the blood, producing a yellowing of the skin, eyes, and mucous membranes.

Two liver cell types, hepatocytes and bile duct epithelial cells, differentiate from a common precursor during embryonic development.⁶³⁴ In the duck both cell types are targets of hepadnavirus infection.^{192,249,373,494} One early study⁴⁵ suggested this was also true in humans, though later reports have not yet confirmed this observation. Other liver cell types do not appear to be infected.

Hepatocytes are long lived, with a half-life exceeding 6 months under normal conditions, and a correspondingly low proliferation rate.^{227,342,423,622,739,766} Though hepatocytes are a self-renewing population in the normal liver, under conditions of severe injury or where hepatocyte proliferation is blocked—for instance by a toxic chemical—facultative progenitor cells, considered to be located in the Canal of Hering, may give rise to oval cells that proliferate and ultimately differentiate into hepatocytes.^{143,180,183,640,705,706} Progenitor cells are also found in the bone marrow,⁴⁸⁹ though their quantitative contribution to hepatocyte replacement and relationship to progenitor cells attributed to the Canals of Hering is unclear. Hepatocyte replacement in response to killing of infected hepatocytes by antiviral cytotoxic T cells (CTL) during acute, transient infections appears to be primarily through division of other hepatocytes.^{306,308,670} Replacement from progenitor cells, with the appearance of oval cells in the lobule, is more evident during late stages of chronic infections, by which time the liver may be highly damaged,^{203,272,589} but hepatocyte proliferation also occurs, and the relative contribution of the two pathways to hepatocyte replacement during late phases of chronic infections has not been determined.

When the liver is injured through killing of hepatocytes, hepatic stellate cells, located in the space of Disse, will respond by producing collagen fibers.^{448,545} During chronic infections the persistent injury due to CTL killing of hepatocytes leads to persistent deposition of collagen, building up fibrous tissue that can evolve to cirrhosis, a condition that distorts the lobular structure, disrupts normal blood flow through the liver, and can lead to death due to liver failure. The progression to cirrhosis may be interrupted, and even reversed, if the infection is controlled by antiviral therapies.^{396,524,581,588,788}

A number of studies suggest that the liver can regulate or at least protect itself against the host immune response. First, in some species including rats, pigs and mice, liver transplantation between allogeneic animals induces tolerance to grafts of other tissues from the same donor that would normally be rejected, suggesting that the liver has immunoregulatory properties, possibly attributable to hepatic dendritic cells.^{702,704} Second, a number of different cell types in the liver appear to have the ability to present antigen in a suboptimal context, in some cases leading to immune tolerance or a weak immune response.^{139,703} Third, the immune response to a number of human viruses that appear to productively infect only hepatocytes—including HAV, HBV, HCV, and hepatitis E virus (HEV) in humans—only becomes robust enough to induce high levels of cell death and virus clearance 4 to 8 weeks after infection, during which time the entire hepatocyte population may become infected. A similar pattern has been seen following DHBV infection of ducks and WHV infection of woodchucks. These observations suggest that scanning of hepatocytes by the immune system is low, and has been attributed to low expression of major

histocompatibility class I (MHC I) genes and poor access of circulating lymphocytes to hepatocytes, despite the occurrence of fenestrations in the liver endothelial cells. The possibility that liver cells other than hepatocytes may induce at least partial tolerance to viral antigens could also contribute to the prolonged course of transient and chronic infections.

Other Sites of Hepadnavirus Infection

The best evidence for replication in cells other than hepatocytes comes from studies of ducks infected with DHBV. Replication in the extrahepatic sites has been observed during chronic DHBV infections established *in ovo*^{163,251} or following inoculation of young ducklings.^{192,201,302,304,305,441} CCC DNA and typical DHBV DNA replication intermediates, with abundant single-stranded DNA (ssDNA), are found not only in liver, but also in pancreas and kidney of chronically infected ducks,^{201,249,271,304,683} as well as in the yolk sac during embryonic development.⁶⁸⁴ Viral DNA also accumulates in the spleen, due to passive accumulation of virus by follicular dendritic cells³⁰⁴; evidence for DNA replication intermediates⁶⁸³ and CCC DNA²³⁵ in the spleen has also been reported, though DNA replication intermediates were not observed in the latter study. The site of DNA replication in the kidney appears to be the proximal tubular epithelium, though infection of glomeruli is also suggested (Fig. 68.14).^{201,249,304} Viral DNA replication in the pancreas appears restricted to a small subset (~1%) of exocrine cells but a majority of endocrine cells,^{142,176,201,249,248,304} which in ducks are localized to alpha and beta islets. Infection of bile duct epithelial cells of the liver also occurs^{249,494} and studies with primary cell cultures suggest that these are sites of DHBV reproduction *in vivo*.³⁷³

Extrahepatic infection has also been studied in chronically infected woodchucks. Gel electrophoresis and Southern blot analysis demonstrated typical viral DNA replication intermediates in the liver and, at an approximately 10-fold lower level, in the spleen. Though typical replicative intermediates were not demonstrated at other sites, ~1,000-fold lower amounts of RNA and total episomal viral DNA than in the liver have been reported in kidney, pancreas, thymus, bone marrow, testes, and ovary,^{336,337,506} suggesting possible infection; in addition, some cells in these latter tissues appeared to contain viral nucleic acids by *in situ* hybridization. It remains unclear, however, if these observations of low levels of viral nucleic acids, outside the woodchuck liver, reflect actual infection or passive accumulation. The most convincing evidence of extrahepatic infection in the woodchuck was obtained from studies with PBLs of WHV-infected woodchucks. Although PBLs did not replicate WHV *in vivo*, they produced typical viral DNA replication intermediates and released virus when stimulated with lipopolysaccharide *in vitro*, and thus appear to be latently infected *in vivo*.^{333,335}

Early immunohistochemical studies of human tissues other than the liver suggested that, as in the duck, exocrine and endocrine cells of the pancreas may be infected.^{632,789} Evidence for DNA replication intermediates in the spleen was also described for humans¹⁵⁸ and chimpanzees,³⁹⁷ though we are unaware of any recent follow-up studies. Evidence for infection,^{91,267,364,398,527,528,550,590,627} gene transcription, and viral replication in peripheral blood mononuclear cells has been reported.^{19,59,242,497} Data in support of infection in bone marrow, as evidenced by the presence of HBsAg and 3 kbp RC DNA, but not DNA replication intermediates, has also

FIGURE 68.14. Sites of virus replication in the DHBV-infected duck.

Tissue sections of liver, kidney, pancreas (exocrine) and spleen, immunoperoxidase stained using an antibody to the DHBV surface antigen (*brown stain*), and counterstained with hematoxylin. Virtually all hepatocytes are infected in the liver. Glomerular infection is illustrated in the kidney (*arrow*). Infection occurs in a few percent of exocrine cells in the pancreas. The reason that some but not all exocrine cells in the pancreas are targets of infection is unknown. Accumulation of viral surface antigen is found in follicular dendritic cells in the spleen but is not believed to represent actual infection. Bar = 50 μ M. (Courtesy of Dr. Allison Jilbert, Institute of Medical and Veterinary Sciences, Adelaide, Australia.)

been presented.^{549,591} The idea that any of these observations reflect actual infection of blood cells, however, has been challenged by a study that failed to detect CCC DNA in these cells. This suggests instead that viral DNA and antigen signals—and, by inference, virus replication reported in these studies—arose from observations of passively adsorbed virus.³³¹ This interpretation has itself been challenged⁶⁶³; the issue remains unresolved.

As independent support for the idea that some human PBMCs are infected, it has been proposed that latently or actively infected blood cells are the source of HBV in post-transfusion hepatitis cases attributed to blood donors with a history of transient HBV infection.⁴⁶¹ However, small amounts of circulating virus originating in other donor tissues, including the liver, have not been ruled out as a cause.^{369,574,790,791} Thus, at present it seems clear that virus, or at least viral DNA, can persist in a variety of tissues of a recovered individual even though the liver is no longer overtly infected. This was shown convincingly in studies in which HBV carriers in liver failure were xenotransplanted with baboon liver, which is resistant to HBV infection.³⁶⁰ Virus DNA persisted in extrahepatic sites for the 2-month follow-up. Whether this persistence reflects active virus replication remains unclear. The question of whether PBMCs or any other site outside the liver of HBV carriers are actually infected, or simply accumulate HBV that was produced in the liver, remains elusive.

Immune Response to Hepadnavirus Infections

HBV infection, replication, and virus shedding are not cytopathic to hepatocytes. This may be another reason the immune response to infected cells is slow to evolve, often not appearing until weeks after essentially every hepatocyte is infected,^{306,308,701,760} which may take weeks to months depending on the infecting viral dose. The result of this massive infection is that a strong immune reaction, with killing of large numbers of hepatocytes, is typically seen during the clearance phase of an infection.⁶⁷⁰ About 95% of immunocompetent adults are able to mount such a response, resolving the infection within

a few weeks once clearance begins. Unfortunately, about 5% of adults and most children under the age of one year are unable to resolve the infection (Figs. 68.15 and 68.16). Instead, chronic hepatitis B with ongoing liver injury may occur, mediated by a T-cell immune response targeting hepatocytes that express viral antigens.^{41,117,208} Chronic infections, with persistence of readily detectable levels of serum virus and surface antigen particles, are generally life long. In chronically infected patients, a certain degree of T-cell function defect is reported, which in turn may be responsible for viral persistence. It is suggested to result from T-cell exhaustion by high antigen concentrations, which promotes HBV-specific T-cell dysfunction by affecting phenotype and function of peripheral and intrahepatic T cells.^{150,188}

Nonetheless, virus titers in the blood often decline during the course of a chronic infection, from as high as 10^{10} per ml to as little as a few hundred per ml. The cause of this decline has not been determined. One possibility is that antiviral cytokines produced during chronic hepatitis suppress virus replication,⁴⁶⁰ as also seems to occur during the clearance phase of transient infections.^{308,670,701,760,762} Another possibility, not exclusive of the first, is that killing of infected cells by antiviral CTLs selects for the survival of hepatocytes that have lost the ability to support high levels of virus replication.⁴⁴²

Results of placebo-controlled trials of antiviral agents suggest that approximately 5% of patients each year experience a spontaneous virus clearance and enter the remission/inactive hepatitis phase.^{162,349,433,787} However, unlike clearance of a transient infection, the serum of a chronic HBV carrier, undergoing spontaneous remission, generally remains HBsAg positive, most likely because many hepatocytes contain integrated viral DNA with an intact S coding region.

Immune Response in Transient Infections

The mechanisms of clearance of transient infections have been investigated in detail in clinical studies as well as through the use of experimental models. Viral clearance appears to require the coordinated action of several components of the immune response^{229,446,670,762,781}: Possibly the innate immune response

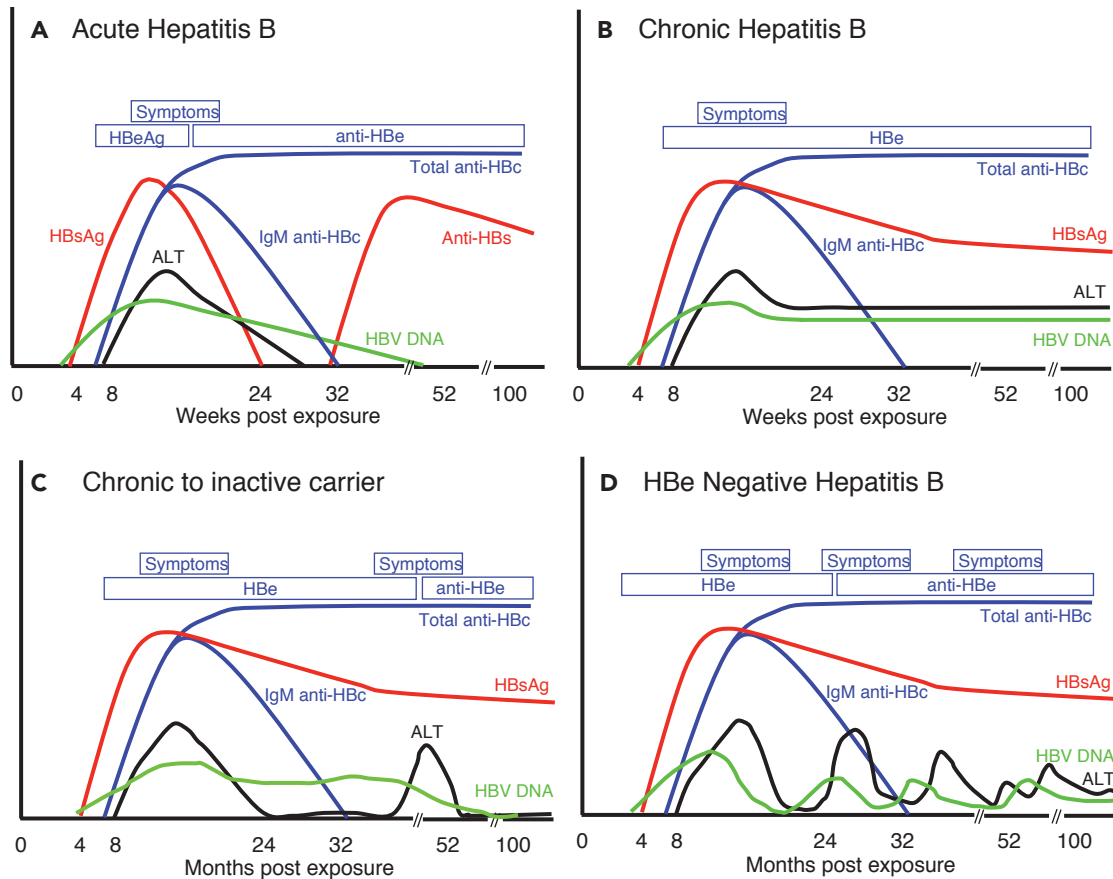

FIGURE 68.15. Serological profiles of HBV infections. **A:** Laboratory diagnosis of acute hepatitis B. Acute hepatitis is diagnosed in patients with jaundice or fatigue and high ALT levels. Evidence of acute HBV infection is obtained by the detection of HBsAg and anti-HBc IgM antibody. Viral replication is authenticated by the detection of serum HBeAg and HBV DNA. Resolution of infection is accompanied by the decline in viral load, seroconversion to anti-HBe, and normalization of ALT levels. Subsequently, HBs seroconversion is observed and represents a serologic marker of the cure of the infection. **B:** Laboratory diagnosis of chronic hepatitis B associated with wild-type virus infection. Chronic HBV infection is diagnosed by the persistence of serum HBsAg and markers of viral replication (i.e., serum HBeAg and HBV DNA). Depending on the phase of disease, ALT levels may be normal or elevated. **C:** Laboratory diagnosis of transition of chronic hepatitis B to the inactive carrier state. HBe seroconversion is associated with the loss of serum HBeAg, the appearance of anti-HBeAb, the decline of serum HBV DNA levels, and the normalization of ALT levels. A flare in ALT levels sometimes precedes it, suggesting that HBe seroconversion may be associated with an immune-mediated hepatocyte lysis. HBe seroconversion is associated with an improved clinical outcome and the patients are classified inactive carriers. **D:** Laboratory diagnosis of HBeAg-negative chronic hepatitis. In some patients, pre-C mutants are selected at the time of HBe seroconversion, and the disease continues to progress with a typical fluctuation of serum HBV DNA and ALT levels. This stage of chronic hepatitis B, which is frequent in the Mediterranean basin, is usually referred to as HBeAg-negative chronic hepatitis B.

mediated by NK and NKT cells, though a study of experimental HBV infection of chimpanzees suggests that HBV infection, *per se*, may not induce an innate response in the liver⁷⁶⁰ (however, see 169, 187); a cytotoxic response by CD8 positive cells recognizing infected hepatocytes expressing viral antigens; a noncytolytic response whereby the CD8 positive cells and other, nonantigen-specific, cells recruited to the sites of inflammation⁶⁴¹ produce TH1 cytokines such as IFN- γ , tumor necrosis factor alpha (TNF- α), and interleukin 12 (IL-12) that exhibit a direct antiviral effect, suppressing virus reproduction in the infected liver; the production of neutralizing antibodies to prevent infection of recovered, or newly differentiated, hepatocytes, by residual virions; cell lysis and apoptosis and compensatory proliferation to generate new uninfected cells that will repopulate the liver.

While there is a consensus on the occurrence and presumed importance of different effectors, their precise role and the order of events is still debated. For instance, antibodies to the viral envelope (anti-HBs) are often not detectable until after virus clearance from the liver, so their requirement during the resolution phase of transient infections, if any, has remained obscure.^{186,308,553} The possibility that antibodies are responsible for disappearance of virus from the serum as clearance from the liver begins has not been directly ruled out, as even low levels of antibody might be enough to bind all circulating virus and facilitate removal from the serum. However, a more attractive hypothesis is that IFN- γ and/or other cytokines released by CTLs, CD4+ T cells, and macrophages are sufficient to rapidly shutdown viral DNA synthesis and, consequently, virus

FIGURE 68.16. Natural history of hepatitis B. Following acute infection, approximately 95% of adults and 5% to 10% of newborns recover, while the remainder evolve towards chronic viral infection. Depending on the vigor of the immune response, chronic infection can follow several phases including immune tolerance, chronic hepatitis (immune clearance phase), the inactive carrier state, and a reactivation phase. These phases may not be stable over time, and patients may evolve from one phase to the other. The major risk of chronic hepatitis is the evolution towards cirrhosis and hepatocellular carcinoma (Fig. 68.17).

production by blocking assembly of DNA replication complexes (viral capsids).^{238,521,526,582,613,614,761}

In HBV transgenic mice that produce virus in hepatocytes, a major role for cytokine mediated, noncytolytic processes in the clearance of viral replication intermediates from the cytoplasm—including DNA replication intermediates, mRNAs, and proteins—has been demonstrated.²²⁹ However, the interpretation of these findings is complicated by the fact that clearance occurs within a few days of induction of an antiviral response (e.g., by adoptive transfer of HBsAg-specific CTLs) and without the need for large amounts of cell death, whereas clearance in infected hosts is relatively slow and involves significant amounts of hepatocyte destruction.^{239,446,670,762} Moreover, the mice used in these studies did not produce CCC DNA, the nuclear species that maintains the infection.

Results of a subsequent study with transgenic mice that do produce CCC DNA suggested that this DNA is sensitive to noncytolytic purging by antiviral cytokines,¹³ though the contribution of hepatocyte death in this transgenic line is unclear.⁵⁵² Studies of acute infection of chimpanzees have also been interpreted to argue the importance of noncytolytic clearance of HBV DNA replication intermediates and CCC DNA but, again, interpretation of the CCC DNA decline is unclear because of the difficulty of quantifying hepatocyte destruction throughout the course of viral clearance.^{233,701,762}

One study, using the woodchuck model of HBV, showed that a substantial fraction of hepatocytes in the recovered liver originated from hepatocytes that were infected, indicating a mechanism for curing these infected cells.⁶⁷⁰ This and another study⁴⁴⁶ also showed that a substantial amount of hepatocyte turnover occurred during resolution of a transient infection. However, it still remains unclear if this hepatocyte turnover, together with proliferation of the remaining hepatocytes to restore liver mass, were sufficient to completely eliminate CCC DNA, even assuming it does not survive mitosis. In brief, a role

for cytokines in the shutdown of virus replication appears settled, but their direct role, if any, in destruction of CCC DNA, is undetermined.

Loss of CCC DNA is not induced in cell culture by cytokines (IFN- α , IFN- γ , TNF- α) that are able to induce a block to assembly of DNA replication intermediates.^{613,614,808} Moreover, CCC DNA appears to be stable, with no evidence for a short half-life in the infected liver. Thus, several competing scenarios for CCC DNA loss have emerged. One theory is that CCC DNA degradation within infected cells occurs during the clearance phase of an infection by a process that has not yet been reproduced in cell cultures. Another theory is that CCC DNA is only lost through cell death. Assuming dying hepatocytes are replaced by division of surviving hepatocytes, and new CCC DNA synthesis is blocked, CCC DNA would be distributed to daughter cells during mitosis and diluted out through multiple rounds of division of those hepatocytes that escaped the antiviral CTLs.⁴⁴⁶ A third theory, related to the second, –is that CCC DNA is lost during mitosis. A fourth is that during resolution of infection the dying hepatocytes are replaced, not by division of mature hepatocytes, but through proliferation of uninfected progenitor cells (Fig. 68.13). However, the last possibility appears to be ruled out by observations that infections can resolve without extensive proliferation of hepatocyte progenitor cells and that a substantial fraction of hepatocytes at recovery are derived from hepatocytes that had been infected.⁶⁷⁰ Current evidence does not allow a clear distinction of the other possibilities. The concept of noncytotoxic loss of CCC DNA is attractive, but unproven.

Clinical Manifestations of Chronic HBV Infections and Decisions to Treat

The natural history of chronic hepatitis B (CHB) can be schematically divided into five phases, which are not necessarily sequential (Fig. 68.16).^{178,412} The “immune tolerant” phase is characterized by HBeAg positivity, reflected by high titers of

serum HBV DNA (>2,000 IU/mL, 1IU=5 viruses), normal levels of aminotransferases, and mild or no liver necroinflammation. During this phase, the rate of spontaneous HBeAg loss is very low. This first phase is more frequent and more prolonged in subjects infected perinatally or in the first years of life. Because of high levels of viremia, these patients are highly contagious. The “immune reactive phase” is characterized by HBeAg positivity, lower titers of serum HBV DNA (but >2,000 IU/mL), increased or fluctuating levels of aminotransferases, moderate or severe liver necroinflammation, and more rapid progression of fibrosis compared to the previous phase. This phase may last from several weeks to several years. In addition, the rate of spontaneous HBeAg loss is enhanced, but may occur at a late stage when fibrosis has already developed. This phase may occur after many years of immune tolerance and is more frequently reached in subjects infected during adulthood. 3) The “inactive HBV carrier state” may follow seroconversion from HBeAg to anti-HBe antibody. It is characterized by very low or undetectable serum HBV DNA levels and normal aminotransferases. As a result of immunologic control of the infection, this state confers a more favorable long-term outcome with a lower risk of cirrhosis or HCC. HBsAg loss and seroconversion to anti-HBs antibody may occur spontaneously, usually after several years with persistently undetectable HBV DNA. “HBeAg-negative CHB” may also follow seroconversion from HBeAg to anti-HBe antibody during the immune reactive phase. It is characterized by periodic reactivation with a pattern of fluctuating levels of HBV DNA and aminotransferases and active hepatitis. As discussed in the section Serology of HBV infections, these patients are HBeAg negative, and circulate HBV unable to express or expressing low levels of HBeAg. HBeAg-negative CHB is associated with low rates of prolonged spontaneous disease remission. It is important and sometimes difficult to distinguish true inactive HBV carriers from patients with active HBeAg-negative CHB who, at the time of examination, are in a phase of spontaneous remission. In the “HBsAg-negative phase” after HBsAg loss, low-level HBV replication may persist with detectable HBV DNA in the liver. Generally, HBV DNA is not detectable in the serum and anti-HBc antibodies with or without anti-HBs are detectable. HBsAg loss is associated with improvement of the outcome with reduced risk of cirrhosis, hepatic decompensation, and HCC.

Current clinical guidelines recommend against antiviral treatment during the immune tolerance phase because patients have no, or very minimal, liver disease (inflammation and/or fibrosis) that can be detected by histologic examination of liver biopsies.^{178,412} That is, treatment is costly and the risk of disease progression is considered minimal so long as ALT levels remain within the normal range. Also, the results of therapeutic trials with IFN- α , or with early nucleoside analog inhibitors of the viral DNA polymerase, showed that patients with high HBV DNA load and normal ALT levels have almost no chance of HBe seroconversion or sustained virologic response as a result of treatment.^{178,412} Nonetheless, it remains unclear if subsequent disease progression, particularly to HCC, is dependent on unapparent injury that occurred in the immune tolerance phase. It is possible that treatment guidelines will be revised, as more effective antiviral drugs have become available.

With the current generation of antiviral drugs and treatment guidelines, antiviral therapy is likely to lead to HBe seroconversion and long-term viral suppression/control by the immune system only in patients in the immune clearance

phase (e.g., ~30% vs. a spontaneous rate of ~5%).^{125,787} This on-therapy transition is usually associated with HBeAg seroconversion, in which HBeAg antigen disappears, anti-HBe antibodies appear, and only low levels of viral DNA (<2,000 IU per ml) persist in the serum. HBsAg usually remains at high levels in the serum. Continued production of HBsAg is thought to be mostly due to expression from viral DNAs that have integrated at random sites in host DNA or from persisting low levels of CCC DNA.⁷⁵⁹ Liver histology usually reveals remission of liver disease activity, and arrest of fibrosis/cirrhosis progression as long as viral load remains low and ALT levels remain normal.^{102,161} Even without this immune clearance during antiviral therapy, suppression of virus replication by antiviral therapy may slow or prevent the cumulative liver damage that can otherwise occur during the immune clearance phase of infection, whether or not overt symptoms are present.^{100,178,297,350,351,365,412,434} (Fig. 68.16).

A more favorable outcome of chronic infection is associated with clearance of HBsAg and the appearance of anti-HBsAb. Virologically, this is more like clearance of transient infections, since anti-HBsAb will help prevent virus rebound. As with clearance of transient infections, HBV DNA may still be detected in serum, though generally at very low titers (<10 IU per ml) and in the liver by the presence of low levels of CCC DNA.^{452,759} Also, as with transient infections, such infections may reactivate with immunosuppression. Whether, in the absence of reactivation, residual virus replication contributes to disease progression seems unlikely. Still, while fibrosis and cirrhosis do not appear to progress, these patients remain at significant risk of developing HCC.⁵⁷¹

Emergence of HBV Variants During a Chronic Infection

HBV is under selective pressure from the immune system and HBV variants may emerge over the course of a chronic infection.²³⁴ These variants are generally assumed to facilitate immune evasion in some way and, as might be expected, have been detected throughout the viral genome. Because both B- and T-cell epitopes may be mutated, it is unclear if emergence of these variants occurs through virus spread or selective survival of hepatocytes infected by the mutants, or both. In the setting of the natural history of the disease, the most studied of these mutants are those that no longer express HBeAg. These variants harbor mutations in the pre-core region and/or in the basic core promoter. When this happens, infections are characterized by presence of HBsAg and absence of HBeAg, and HBV DNA levels that are fluctuating, but usually are >2,000 IU per ml. ALT levels may also be elevated and/or fluctuating over time.^{53,245} (Fig. 68.15D). Like HBeAg-positive infections, this form of chronic hepatitis B is associated with a high risk of liver fibrosis, cirrhosis, and HCC.^{53,222,245} Unlike HBeAg-positive infections, treatment endpoints are more difficult to define, since HBeAg seroconversion (see above) cannot be used as a surrogate marker for immune control of virus replication; therefore sustained, therapeutic suppression of HBV replication is the primary objective in this situation.

CLINICAL ASSESSMENT OF HBV INFECTIONS

Laboratory Diagnosis of Infection

Persistence of HBsAg in the blood circulation for more than 6 months is an indication of chronic infection. Loss of HBsAg,

on the other hand, is an indication of almost complete elimination of virus. Antibodies directed against HBsAg are used as a marker of protection against HBV. HBeAg is a serologic marker of active viral replication. Loss of circulating HBeAg and appearance of anti-HBe antibodies (HBeAg seroconversion) may indicate the end of active viral replication and the beginning of clinical resolution of both transient and chronic infections. HBcAg, representing the capsid protein, is highly immunogenic and the appearance in the circulation of anti-HBc IgM is usually the first immunologic sign of a transient HBV infection. Typical serologic profiles of chronic HBV infections are shown in Figures 68.15 and 68.16.

The most rigorous way of determining the presence of circulating virus is to assay for viral DNA. The lower threshold for risk of active hepatitis and liver damage is considered to be around 10^4 viral genome equivalent per ml, equivalent to $\sim 2,000$ IU/mL.^{82,178,125,403} Figure 68.16 shows the evolution of viral load during the natural history of infection and underlines the necessity of highly sensitive and quantitative assays to monitor viral load in the different phases of the disease. In patients who have lost HBsAg from serum and may have an occult infection, virus titers are usually very low, and thus can escape detection even by PCR-based assays.⁵⁷¹

Serology of HBV Infections

The development of quantitative assays for HBsAg detection revealed that chronically infected patients, as well as those at the peak of a transient infection, can have HBsAg titers of $>10^{12}$ particles per ml, or >500 μ g of protein per ml.⁸¹² Clinical assays can detect as little as 0.2 ng (or 0.05 IU/mL) of HBsAg per ml of serum, providing a highly sensitive assay for HBV infection. HBsAg levels in serum were found to correlate with HBV DNA levels during transient infections, but this correlation breaks down during the course of a chronic infection.^{299,492}

Mutations in the S gene, particularly a region known as the “a” determinant (Fig. 68.9), can lead to loss of recognition by the antibodies used in commercial assays.⁸⁵ Major improvement of these commercial assays has been made recently to detect the main S gene mutants. These HBV mutations can emerge primarily in response to therapy, for instance during passive antibody therapy with high titer immunoglobulins, and after HBsAg vaccination of young, HBV-exposed children. The existence of these rare mutant viruses suggests that HBsAg-negative patients with hepatitis of unknown etiology should be tested with a secondary assay, e.g., viral genome detection. Prospective blood donors should also be tested with secondary assays when HBsAg assays yield negative results.

A number of secondary assays are available. IgG reactive to HBcAg is a marker of past or ongoing infection and is therefore found in both resolved infections and in chronically infected individuals. Anti-HBc IgM is typically found during transient infections and may be detected, at low levels, during acute exacerbation of chronic infections^{243,537,812} (Fig. 68.16). Alternatively, HBeAg is generally found in the blood of transiently infected individuals, as well as many chronically infected individuals when they are in the high viral replication phase, particularly the immune tolerant and early immune clearance phases.

Seroconversion to anti-HBe antibody generally occurs during resolution of transient infections.^{32,478,718} As noted, loss

of HBeAg often occurs as well during the course of chronic infections, sometimes but not always with the concurrent appearance of anti-HBe antibodies. Loss of HBeAg from serum, even in the absence of anti-HBe antibodies, usually reflects a decline in the amount of virus in the liver. Thus, the loss of HBeAg in chronically infected individuals, either with or without the concomitant appearance of anti-HBeAg, may signal a major drop in virus titers and a reduction in disease activity as patients enter a remission phase. However, in other patients it may be associated with an ongoing disease activity because it simply reflects immune selection of virus that has lost the capacity to produce HBeAg. This loss, as already noted, is typically due either to stop codon mutations near the 5' end of the pre-C gene or to mutations in the basic pre-C/C promoter (Fig. 68.7).²⁴⁵ Thus, HBe seroconversion is often, though not always, an indication that virus production has either ceased or significantly abated.

Finally, sensitive real-time PCR assays for quantification of viral DNA in serum are available with a cut off as low as approximately 30 to 50 viral genome copies per mL, or ~ 10 IU/mL.^{115,700} The combination of serologic markers, including quantification of HBsAg and HBV DNA in serum, has improved the diagnosis of inactive carriers, which usually have a low viral load (HBsAg $<1,000$ IU/mL and HBV DNA $<2,000$ IU/mL).⁶⁷ In patients who have lost HBsAg in serum after resolution of a transient infection or during the course of chronic HBV infection [i.e., who are HBsAg (–) and anti-HBc Ab (+), either with or without anti-HBs] detection of serum HBV DNA by sensitive PCR assays may reflect the persistence of infected hepatocytes after the clinical resolution of the disease⁵⁷¹ (Fig. 68.16).

HBV Genotype and Infection Outcomes

As discussed, HBV has been divided into eight genotypes, A through H⁴⁹⁸ (Fig. 68.3). Genotype A is found in Western and Northern Europe, as well as in Africa. Some studies suggest that it may be associated with a better response rate to IFN therapy for chronic hepatitis.⁷⁹ Genotypes B and C are found in Asia. Clinical studies have suggested an association of genotype C with a more severe chronic liver disease and a poorer response rate to IFN therapy.^{313,796} Genotype D is observed mainly in the Mediterranean basin and is associated with a higher prevalence of pre-C mutants in chronically infected individuals (i.e., the patients are HBeAg negative)²²² as well as a lower response rate to IFN.⁷⁹ Genotype E is mainly observed in Africa, while genotype F has been identified in South America and Polynesia. Genotype G has been identified in chronic carriers living in France and the United States, and is often found as a co-infection with genotype A.⁶⁶⁵ Finally, genotype H has been described in Amerindians from Central America.

Because of RNA folding constraints placed on the epsilon region of pgRNA, pre-C stop codon mutations that abolish pre-C protein synthesis and, hence, HBeAg production, would also abolish virus replication in some HBV genotypes. This restricts their occurrence to compatible HBV genotypes or by the requirement of compensatory mutations. In practice, these mutations are mainly observed in patients chronically infected with HBV genotype D.³⁸⁹ Patients infected with other HBV genotypes may also present with HBeAg-negative chronic hepatitis B, in these cases mainly caused by mutations in the pre-C/C promoter.⁵⁰⁸ Mutations in the pre-C/C promoter are not HBV genotype restricted.^{222,402,525}

Occult HBV Infections

A form of hepatitis that has generated a lot of debate is so-called occult HBV infection.^{61,81,103,571} Occult infection is characterized by the detection of HBV DNA by PCR in the serum and/or the liver of patients in whom serum HBsAg assays give negative results. Occult HBV infection can be observed in up to 30% of patients with liver disease of unknown etiology. It was shown that the HBV genome of these occult infections is replication competent in tissue culture and that viral suppression observed *in vivo* may be due to epigenetic control of intrahepatic CCC DNA.⁵⁴⁷ It is unclear whether in some or perhaps all such patients the occult infection is actually a serologically cured infection (e.g., 369,463,533,790,791), or whether it is actually the cause of the ongoing liver disease. Occult HBV infections have been reported in a significant proportion of HBsAg-negative patients with HCC.^{61,529,548} However, even here it is possible that a chronic infection had spontaneously resolved after the progression to liver cancer was already fixed, but before appearance of the neoplasm. Thus, it is unclear if occult infections represent a distinct class of infection or fit into the categories discussed earlier. Additional confusion may arise because some infections characterized as occult simply escaped detection due to mutations in the S gene that prevented detection by the serologic assay for HBsAg that was employed. In these patients, in contrast to those so-called occult infections in which a more broadly reactive HBsAg assay failed to detect the infection, HBV DNA titers may be very high.⁵⁷¹

Diagnosis of Acute Hepatitis B

Acute hepatitis, which may occur during resolution of a transient infection or during a hepatic flare in chronic infection, is diagnosed in patients with jaundice or fatigue and high ALT levels. Evidence of HBV involvement is obtained by the detection of HBsAg and anti-HBc IgM. However, other factors need to be considered. For instance, co-infection with hepatitis delta virus (HDV) is evaluated at this stage by assaying for serum HDsAg, anti-HDV IgM, and HDV RNA. Other causes of acute viral hepatitis should be tested including acute hepatitis C virus (HCV) infections, acute HAV, acute HEV, and other rare cases of acute HSV or CMV infections. If all factors suggest involvement of HBV, transient infection is indicated by disappearance of HBsAg in the weeks immediately following the flare of acute liver disease (Fig. 68.15A). It should be

noted, again, that an acute flare on chronic infection can be preceded by months of high-titer viremia but little or no liver disease.

Diagnosis of Chronic Hepatitis B

Chronic HBV infections are usually asymptomatic for most of their course, although patients may complain of fatigue or arthralgias. The diagnosis of chronic hepatitis B is usually made by the detection of serum HBsAg and elevation in ALT levels (Fig. 68.15B).^{178,412} Nausea, loss of appetite, and jaundice may occur during acute hepatic flares (e.g., during the immune clearance phase). However, a hepatic flare may be completely asymptomatic and diagnosed only by a close monitoring of HBV DNA and ALT levels. It is also important to note that an acute rise in ALT levels and other symptoms of acute hepatitis may not always be due to HBV infection. It is necessary to rule out superinfection by HAV/HEV, HCV, or HDV, especially in patients with a high risk for new infection, such as intravenous drug users or patients requiring transfusions. Other causes of chronic liver diseases should be excluded.

PREVENTION AND CONTROL

Antiviral Therapy

Seven therapies have received approval for the treatment of CHB, including interferon alpha (IFN- α), pegylated IFN- α , and several nucleoside(tide) analogs (NUCs), which are viral polymerase inhibitors. They belong to one of three structural groups: L-nucleosides (lamivudine and telbivudine), alkyl phosphonates (adefovir dipivoxil and tenofovir disoproxil fumarate) and D-cyclopentanes (entecavir).

As discussed earlier, antiviral therapy is currently recommended only for patients with active liver disease who have a significant risk of liver disease progression in the short term, and not for patients that do not have elevated ALTs and/or histologic evidence of inflammatory liver disease.^{178,412} To a certain extent this has been mediated by the limited efficacy of antivirals such as lamivudine, to which resistance rapidly develops (Table 68.1). The higher barrier to entecavir and tenofovir resistance may lead to a change in treatment guidelines to include patients who still appear histologically normal or with minimal liver damage. Irrespective of the possible benefits of

TABLE 68.1 Incidence of Drug Resistance During Antiviral Therapy

Drug and patient population	Resistance at year of therapy expressed as percentage of patients					
	Year 1	Year 2	Year 3	Year 4	Year 5	Year 6
Lamivudine	23	46	55	71	80	—
Telbivudine, HBeAg-Pos	4.4	21	—	—	—	—
Telbivudine, HBeAg-Neg	2.7	8.6	—	—	—	—
Adefovir, HBeAg-Neg	0	3	6	18	29	—
Adefovir (LAM-resistant)	Up to 20	—	—	—	—	—
Tenofovir	0	0	0	0	—	—
Entecavir (naïve)	0.2	0.5	1.2	1.2	1.2	1.2
Entecavir (LAM resistant)	6	15	36	46	51	57

Regulation of secretion of the hepatitis B virus major surface antigen by the preS-1 protein. *J Virol* 1987;61:782–786, with permission.)

starting antiviral therapy earlier, there are major reasons for not delaying therapy once active liver disease is diagnosed: if HBV replication and elevation of ALT levels are ongoing, there is a proven risk of progression to cirrhosis and hepatocellular carcinoma (Fig. 68.17).^{396,575,779,799} Antiviral therapy, particularly with NUCs, decreases viral load, normalizes ALT levels, induces a remission of the disease,⁸¹⁰ and reduces the progression of cirrhosis and HCC.^{104,291,396}

Interferon (IFN) Therapy

The principle immunologic treatment for hepatitis B is IFN- α , which has been used since the 1980s. Although IFN- α has a direct antiviral effect, suppressing HBV replication, its major effect is considered immunologic, inducing and/or facilitating a hepatic flare that resolves the infection and establishes immunologic control that prevents virus rebound. This treatment only has lasting effects in patients with immunologically active liver disease, augmenting an already active host response against the virus.

In HBeAg-positive chronic hepatitis B, treatment with standard IFN- α or its pegylated form leads to HBeAg seroconversion, loss of viral DNA, and clinical remission in ~20–30% of patients.^{297,365,495,767} Clinical benefit appears to be long term in these responding patients, including a decreased risk of progression to cirrhosis and hepatocellular carcinoma (HCC). HBsAg loss may occur several years after treatment cessation. However, IFN- α treatment is not particularly well tolerated, provoking a “flu-like” syndrome in many individuals. In addition, IFN- α needs to be injected subcutaneously for 6 to 12 months, and thus causes additional discomfort to the patient. It is, however, the only medication that can be administered with a finite duration.

Nucleoside Analog Therapy

NUC therapy represents the primary choice for treatment of chronic HBV. The effect of treatment with inhibitors of viral DNA synthesis is to stop viral DNA replication within hepatocytes and prevent release of infectious particles into the bloodstream. The half-life of circulating particles is relatively short, around 24 hours, and the decline in virus titers predictable.⁵⁰¹ The half-life of DNA replication intermediates has not been studied in great detail, but is probably a few days. However, the intrahepatic viral CCC DNA that maintains the cellular infections and thus, infected hepatocytes, is cleared much slower, with a half-life in the liver of a few days to several months according to the strength of the host immune response. Therefore, NUC therapies necessitate long-term treatment.^{501,720,759} CCC DNA loss is believed to reflect, primarily, the death of infected hepatocytes rather than intracellular instability, at least in the context of chronic infections.^{196,675,670,672,809} NUCs that inhibit HBV DNA synthesis thus prevent the replacement of CCC DNA, as some infected hepatocytes die and others proliferate to maintain liver cell number.⁸⁰⁹ Unfortunately, but not unexpectedly in view of its history in the treatment of HIV infections, one of the major problems of long-term NUC therapy is the emergence of drug-resistant virus (Table 68.1) The rate of emergence of the mutants depends on their fitness to spread to hepatocytes that have lost the HBV and on the rate of destruction of infected hepatocytes.^{405,811}

Endpoints of Therapy

Therapy must reduce HBV DNA to as low a level as possible, ideally below the lower limit of detection of real-time PCR assays (10–15 IU/ml), to ensure a degree of virologic suppression that will then lead to biochemical remission, histologic

improvement, and prevention of complications. IFN- α - or NUC therapy-induced HBV DNA reduction below 2,000 IU/ml is associated with disease remission. Sustained virus suppression increases the chance of HBe seroconversion in HBeAg-positive patients and the additional possibility of HBsAg loss in both HBeAg-positive and HBeAg-negative patients.¹⁷⁸

Results with Current Therapies

The antiviral efficacy of the currently approved therapies, in terms of viral suppression and clinical endpoints, has been assessed in several studies.^{100,350,365,434} Comparisons between studies are limited due to differences in patient characteristics, baseline HBV DNA levels, study design, and methodologies used to quantify HBV DNA.

In clinical trials, lamivudine achieved higher levels of viral suppression than pegylated IFN- α following 1 year of therapy; however, sustained response rates during the 24-week off-treatment follow-up period were superior for IFN.^{297,365} Furthermore, treatment with pegylated IFN has been associated with improved serologic responses such as HBsAg and HBeAg seroconversion several years after treatment cessation. Moreover, IFN does not induce any form of resistant virus and has been shown to reduce lamivudine resistance during combination therapy.^{297,365}

Resistance to NUCs is complicated by the fact that resistance mutations to one antiviral drug may be at least partially effective against another.⁸¹¹ Thus, resistance to a new drug can emerge more rapidly in patients previously treated with another drug than in treatment-naïve patients (Fig. 68.10).

Cumulative annual incidences of resistance in CHB patients on a single NUC, with no prior history of NUC therapy, are shown in Table 68.1. Lamivudine resistance occurs frequently and is observed in up to 80% of patients treated for 5 years.⁴¹¹ Telbivudine resistance is slower to emerge, but rates are substantial, with 25% of HBeAg-positive and 11% of HBeAg-negative patients experiencing virologic breakthrough due to resistance after 2 years of treatment.³⁹³ Among adefovir-treated patients, the cumulative incidence of resistance over 5 years has been reported at 29% for HBeAg-negative patients and 42% for HBeAg-positive patients.^{244,432} No tenofovir resistance has been observed after 4 years of treatment.⁶⁴⁵ Long-term studies of entecavir monotherapy in nucleoside-naïve patients have demonstrated that resistance remains low through 6 years of therapy, at 1% to 2%.¹⁰¹ In brief, current studies indicate that entecavir and tenofovir are the most potent of the currently available NUC antivirals.

The consequences of developing resistance to NUCs have been well documented. Patients treated with lamivudine or adefovir who develop virologic breakthrough of drug-resistant mutants frequently experience acute exacerbations of disease (ALT elevations) and more rapid progression to acute liver failure or HCC.^{396,411} Furthermore, the emergence of drug resistance and the subsequent need for rescue therapy increases the risk of development of multidrug-resistant HBV (Fig. 68.10). For example, entecavir is effective in patients with adefovir resistance and patients with prior lamivudine treatment who had not developed resistance, but not in patients with proven lamivudine resistance.⁵⁷⁶ Similarly, tenofovir has also been shown to be effective for patients with lamivudine resistance and an incomplete response to adefovir, but not necessarily for patients with adefovir resistance.^{38,530} In case of treatment failure, adaptation

of therapy should be made as early as possible using a drug that does not share the same cross-resistance profile.⁸¹¹

Nucleoside Analog Therapy of Difficult-to-Treat Patients

In patients with end-stage cirrhosis and little liver reserve, IFN treatment is not recommended because it increases the risk of liver failure due to immune killing of the remaining functional hepatocytes. In contrast, NUC therapy can benefit these patients, with control of viral replication, accompanied by significantly improved liver functions.^{394,395}

In liver transplant recipients with HBV recurrence in the liver graft, IFN is also contraindicated because of the risk of inducing liver graft rejection. Both tenofovir and entecavir have shown a clinical benefit that seems to be superior to that obtained with earlier NUCs.^{127,536,607} The prevention of HBV recurrence after transplantation relies at present on pretransplantation antiviral therapy with NUCs to decrease viral load, and posttransplantation hepatitis B immunoglobulin (HBIG) and NUC administration to prevent HBV recurrence. With such prophylactic protocols, the risk of HBV recurrence has decreased from 20% to 30% to below 5%.

Other Drugs in Clinical Development

Currently, there are only a few new treatment strategies in clinical evaluation. These include the combination of IFN with NUCs (tenofovir and entecavir) with high barrier to resistance, as well as the combination of NUCs with immunomodulation strategies (i.e., IL-7 with or without vaccine therapy). Other drugs targeting viral entry, nucleoside assembly, or viral morphogenesis are undergoing preclinical evaluation.

VACCINES

Current Vaccines

Vaccines containing S alone are produced by processing of HBsAg purified from plasma of HBV carriers as well as from the yeast *Saccharomyces cerevisiae* expressing S from recombinant DNA. In Europe an M/S recombinant vaccine, containing both the S and M envelope proteins expressed in a Chinese hamster ovary cell line, is also available. Both vaccines contain the immunodominant “a” determinant of HBsAg in S.

These vaccines are administered in the deltoid muscle and are highly immunogenic, inducing a protective anti-HBs antibody titer (>10 IU per ml) in more than 95% of children or young adults.^{12,366,736} Two schedules of administration are approved: 3 initial injections at 1-month intervals and a booster at 12 months; or 2 initial injections 1 month apart followed by a booster at 6 months. About 5% of those vaccinated fail to respond with development of antibodies to the vaccine. Several factors seem responsible, including genetically determined nonresponsiveness, age over 40 years, high body mass index, and immunosuppression.^{12,366,736} Vaccination is associated with rare side effects, most commonly pain or soreness at the injection site. Neurologic disorders such as multiple sclerosis, Guillain-Barré syndrome, and transverse myelitis have not been causally linked to the HBV vaccine.^{17,131}

The efficacy of protection against HBV infection has been established in large clinical studies of high-risk populations such

as homosexual men, healthcare workers, and infants born to HBsAg-positive mothers.^{12,366,736} Protection was evident when anti-HBs Ab titers were above 10 IU per ml. Several years after vaccination, the anti-HBs Ab titer may decline to undetectable levels but immunity persists, suggesting the existence of an immunologic memory.^{12,366,736} Based on these results, a booster is not recommended in healthy individuals who are not constantly exposed to HBV infection.

A universal vaccination program has been recommended by the WHO with the goal of eradicating HBV. In Taiwan and Italy, mass vaccination of infants has not only decreased the incidence of HBV infection and the prevalence of chronic carriers, but also the incidence of HCC.^{96,97,105,664} In addition to implementation of a universal vaccination program for young children, it will be important to perform antenatal screening of pregnant women for HBV infection and to administer vaccine and HBIG to neonates of HBV-positive mothers.^{12,366,736} Catch-up vaccination of 11- to 12-year-old children, high-risk adolescents and adults—along with HBV screening and vaccination of household contacts of chronic carriers and immigrants to hyperendemic regions—will also be important. Finally, resources need to be in place for HBIG and vaccine administration after contaminated needle-stick injury in unprotected individuals.

Based on the difficulties of treating chronic HBV infection—including high cost, the emergence of drug-resistant mutants, and the risk of development of HCC—the efficacy of prevention through vaccine is a strong incentive for the continuation of the mass vaccination program worldwide.⁴⁴⁷

Vaccine Escape Mutants

Vaccine escape mutants have been reported in follow-up studies of individuals receiving HBsAg vaccines composed of the S protein. Vaccinated individuals typically mount a very strong antibody response to the immunodominant “a” determinant (Fig. 68.9) located in the exposed hydrophilic domain of S between amino acids 99 and 168.^{171,540,660} The “a” determinant itself has been mapped from amino acids 124 to 147,^{18,42,66,559,755} though some authors have extended the domain a few amino acids upstream and/or downstream. Two loops bounded by disulfide bridges are inferred by some authors to exist between cys124 and cys137, and cys 139 and cys147, but other pairings have also been suggested.¹¹² The “a” determinant is highly conserved and is found in all genotypes of HBV.⁴⁹⁸ Vaccine escape represents a distinct phenomenon, in which a vaccinated individual develops chronic HBV infection and is seropositive for HBsAg despite the presence of antibodies to the group-specific “a” determinant of HBsAg that were induced by the vaccine. This is possible because HBsAg present in the serum of these patients lacks the group-specific “a” determinant, generally as a result of missense mutations in the region of S that encodes amino acids 124 to 147 (Fig. 68.9).

Most studies of vaccine escape have involved at-risk children and infants who were either vaccinated or received vaccine plus HBIG, which is strongly reactive to the “a” determinant of HBsAg. For instance, in the 1980s a follow-up study of childhood vaccination in Italy revealed vaccinees who became HBsAg positive despite the presence of a strong antibody response to HBsAg. The incidence was rare, involving about 2% of the children of HBsAg-positive mothers, or with HBsAg-positive family contacts.^{87,800} More detailed analysis of virus from one patient

revealed a point mutation encoding a G145R substitution at amino acid 145 of the S protein.⁸⁷ Analysis with monoclonal antibodies to the “a” determinant of wild-type HBV revealed a loss of binding to the mutant HBsAg.^{87,756} Subsequent studies in other populations with high HBV endemicity confirmed the rare occurrence of vaccine escape mutants in children, including the glyc145arg substitution in “a,” other substitutions or insertions in “a,” and mutations within the external hydrophilic domain, but outside of “a.”^{86,191,273,286,317,374,509,512,513,776} Vaccine escape variants have also been detected in unvaccinated children and adults with circulating virus as well as anti-HBs,^{273,776} possibly reflecting past or concurrent infection with wild-type and mutant virus. One concern is that these mutant viruses will become an increasing fraction of the pool of HBV carriers and an increasing risk for vaccinated individuals,²⁷³ though recent studies suggest this scenario may not be correct.²⁷⁴

ANIMAL MODELS OF HBV INFECTIONS

Chimpanzee

Higher primates, including the chimpanzee, are susceptible to HBV. The chimpanzee in particular has been employed periodically to study virus transmission, the host response, and vaccination. Viral hepatitis was known to occur in captive chimpanzees even prior to the discovery of HBV, and early studies showed the presence of Australia antigen in the serum of a fraction of captive animals, including evidence of chronic infections.⁴⁵¹ Chronic infections are associated with persistent liver inflammation.^{173,343,636} Subsequent studies showed that chimpanzees were susceptible to experimental infection with HBV^{21,39,212} and were protected from infection by the vaccine comprised of HBsAg purified from virus carriers.^{80,344,449,566} Chimpanzees were also used to demonstrate the efficacy of recombinant vaccines comprised of surface antigen particles produced in yeast,^{43,204,606} and have been used, for example, to test other approaches to preventative or therapeutic vaccination, including peptide antigens,^{293,485} virus core protein,^{294,477} and virus vectors.^{414,471,523} Recent experiments demonstrated vaccine escape of lamivudine-resistant HBV variants, due to the fact that mutations creating drug resistance mutated the overlapping S gene, confirming observations made in vaccinated infants and liver transplant recipients who experienced breakthrough infections.³⁰⁹

In other areas it was shown, shortly after the first cloning of the HBV genome, that cloned DNA was infectious in chimpanzees,⁷⁶³ as was HBV produced by cultures of human^{4,679} and rodent cells,⁶³⁰ and that transient infection in chimpanzees followed a similar course to transient infection in humans.^{21,39,40,270} However, for ethical reasons, as well as cost, use of the chimpanzee to address questions about the biology and immunology of infections has been limited. Early studies suggested that HBV was able to replicate in the spleen to a limited extent,³⁹⁷ though follow-up studies to determine if the observations reflected actual replication or passive accumulation of virus remain to be done. More recent studies have demonstrated the key roles of CD4 and CD8 T cells in the clearance of transient HBV infections,^{16,701,762} the apparent lack of induction of innate immune responses by the primary infection,⁷⁶⁰ and the existence of clonal hepatocyte proliferation in chronic liver disease.⁴⁴⁴ The chimpanzee has not so far proven to be a model for

HCC, as only a few cases in HBV-infected chimpanzees have been reported, and only in chimpanzees co-infected with either HDV or HCV.⁵⁵⁴ It is possible that the failure to detect HCC reflects the limited numbers of chimpanzees that have been subjected to long-term studies.

Woodchuck and Ground Squirrel

WHV was discovered in woodchucks housed in the Penrose Laboratory of the Philadelphia Zoo,⁶⁷⁷ and quickly found to be prevalent in woodchucks trapped in the mid-Atlantic states,⁷²⁷ but not in woodchucks trapped in upstate New York.^{133,695,768} The correlation seen in early studies between chronic WHV infection and HCC⁶⁷⁷ reinforced the conclusion from concurrent studies of human populations^{49,450,560} suggesting that chronic hepadnavirus infection was a cause of liver cancer. Investigations with captive woodchucks showed that WHV induced HCC in essentially 100% of neonatally infected woodchucks within 2 to 4 years, and in 20% of those that resolved the infection after neonatal inoculation.^{338,692,693}

Shortly after the discovery of WHV, a related virus, ground squirrel hepatitis virus (GSHV) was discovered in California (Beechey) ground squirrels.⁴³⁵ Like WHV, GSHV causes HCC in chronically infected animals. However, the course of infection is milder, the onset of HCC is delayed beyond 4 years, and the incidence is lower—around 50%.^{141,436,438} GSHV infection also runs a milder course than WHV when inoculated into woodchucks and, again, the onset of HCC is delayed, suggesting that the difference in pathogenesis between WHV and GSHV in their natural hosts might be a property of the viruses rather than the hosts.⁶¹⁶

In recent years, more research has been done with the woodchuck than the ground squirrel, primarily because a colony of woodchucks at Cornell University was established and extensively used for preclinical evaluation of antiviral compounds,⁶⁹⁵ and because uninfected and chronically infected woodchucks were available from commercial sources. Similar to findings with human HBV carriers treated with lamivudine, treatment of carrier woodchucks with nucleoside analog inhibitors of WHV replication—clevudine or entecavir—appears to delay the onset of HCC.^{129,334} A current deficiency of the woodchuck model, aside from the technical difficulties in managing a large nondomesticated animal in a laboratory setting, is the lack of reagents available to study woodchuck gene expression, including antibodies to characterize the immune response to transient and chronic infections. Attempts to correct this deficiency^{3,217,239,457,458,462,778} are still at an early stage.

Ducks

The domestic duck was the first avian species discovered to be infected with an HBV-like virus,^{445,749,807} DHBV, and the first host in which virus replication was studied in detail. The reason is that DHBV is widely distributed in domestic flocks, chronically infecting 10% or more of the birds. Therefore, infected animals were readily available for research. Moreover, the infection is generally apathogenic because spread is predominantly vertical rather than horizontal.^{445,504} DHBV replicates in the yolk sac⁶⁸⁴ and rapidly spreads to the developing embryo, with replication detected in the liver as early as 4 to 5 days of embryogenesis⁷³⁰ (ducks hatch at 28 days). As a result, the congenitally infected ducks are immunotolerant to the virus and do not develop significant cellular or humoral immune responses

or liver disease due to their infection, despite the fact that all hepatocytes are producing virus, and sera and liver contain high titers of virus and virus replication intermediates, respectively.

DHBV infection of domestic ducks shares many similarities with orthohepadnavirus infections. There are some notable differences, however. First, perinatal and congenital DHBV infections do not appear to lead to chronic liver disease, cirrhosis, or HCC. A high incidence of HCC has been reported in domestic ducks in the People's Republic of China, but is likely due to aflatoxin exposure rather than DHBV infection.¹⁶⁸ The lack of HCC due solely to DHBV infection may reflect the fact that chronic infection in ducks is usually established under conditions in which the immune system does not respond to the infection, enforcing the idea that liver disease is the result of the host antiviral response. It needs to be kept in mind, however, that prospective studies of more than 3 to 4 years have not been carried out, and this does not extend to near the potential life span of these ducks, which probably is in excess of 10 years. Thus, cirrhosis and HCC developing later in life would have been missed. One reason these long-term studies have not been pursued is that ducks develop a chronic liver disease that is unrelated to DHBV infection.⁴⁴³ Secondary amyloid disease of the liver,^{136,137,579} a condition characterized by the aberrant, extracellular deposition of fibrils of serum amyloid A protein, a secretory protein produced by hepatocytes, often appears in 50% or more of the ducks in a cohort by 6 to 9 months of age, and eventually replaces the cellular population of the liver by a proteinaceous mass,²³⁷ leading to liver failure.

A second feature distinguishes DHBV infection from typical orthohepadnavirus infections. Following inoculation of adult chimpanzees with HBV or woodchucks with WHV, a viremia of 4 to 8 weeks can develop before the infection begins to resolve. Inoculation of adult ducks or ducklings more than about 3 weeks of age leads to the rapid appearance of virus neutralizing antibodies, so that a viremia is never detected beyond a few days postinfection, and the number of infected hepatocytes is largely determined by the amount of virus in the inoculum.^{302,306} This observation reinforces the notion that maintenance of DHBV in nature is largely dependent on *in ovo* transmission.

Viral DNA replication intermediates (viral capsids) in infected duck liver are easy to isolate and study^{250,671} because, in contrast to mammalian hosts, ducks infected *in ovo* do not contain large amounts of antibodies that can bind to and aggregate the capsids. As discussed earlier, several steps in viral DNA replication, including reverse transcription and priming of plus- and minus-strand DNA synthesis, were first characterized using liver and sera from DHBV infected ducks.^{399,400,468,469,671}

Primary duck hepatocyte cultures have also played a key role in our current understanding of hepadnavirus replication, facilitating analysis of early steps in the virus life cycle, including the finding that CCC DNA copy number increases early in infection⁷²⁵; that copy number amplification, at least for DHBV, is negatively regulated by viral envelope proteins^{675,676}; that overproduction of CCC DNA is cytopathic³⁸⁰; and that CCC DNA is produced via reverse transcription rather than semi-conservative DNA synthesis.⁷²⁴ Many of these experiments have not yet been possible with the orthohepadnaviruses.

The duck model has also been used to characterize transient and chronic infections and antiviral therapies. Early studies with DHBV showed that a hepadnavirus could be cleared even after

infection of the entire hepatocyte population,³⁰⁶ ruling out the possibility that chronic infection occurred simply because the immune response did not control virus spread before the entire hepatocyte population was infected. Subsequent experiments revealed the very high specific infectivity of DHBV and, by inference, other hepadnaviruses, showing that nearly 100% of virions could be infectious,³⁰⁵ as recently shown with HBV.¹⁶ Analysis of ducks that were chronically infected via congenital transmission or by inoculation at birth, and therefore mounted either no response or a minimal immune response to the infection, provided some of the early evidence that hepadnavirus infections were nonpathogenic.^{249,303} Like the woodchuck, the duck model has also been extensively used in preclinical trials of investigational antiviral drugs.^{5,6,154,192,196,197–198,202,264,289,318,345,368,372,417,418,440,465,474,496,505,511,620,626,652,680,709,721,722,743,752}

Transgenic Mice

Transgenic mice have been developed to study the consequences of liver-specific expression of the entire virus^{14,121,181,232,269} as well as individual gene products. Individual products that have been examined include HBsAg,⁴⁶⁴ core,²³¹ L,¹¹⁹ S^{120,555} and X.^{324,332,376,774,792}

One of the earliest studies with HBV transgenic mice involved strains that produced viral envelope proteins. Of the three envelope proteins, S is the most abundant and L the least, reflecting in part the relatively weak PreS promoter in comparison to the S promoter.²⁵⁸ When transcription of the PreS mRNA was under the control of a relatively weak, nonviral promoter, and M and S under control of the S promoter, HBsAg was produced and secreted into the blood stream, just as in a natural infection. However, when a stronger promoter was used to direct synthesis of PreS mRNA, a very different result was obtained. Secretion of HBsAg was blocked and, instead, HBsAg accumulated in the ER, leading to the proliferation of intracellular membranes to give the hepatocytes a ground-glass appearance.¹¹⁸ This lesion had been previously observed in human liver chronically infected with HBV and is characterized by the accumulation of the 22-nm diameter, rod-like form of surface antigen in the cisternae of the ER.²¹¹ Cell-culture studies confirmed that ER retention was due to overexpression of L compared to S.^{453,519}

Analysis of transgenic mice overexpressing L revealed morphologic distortion of hepatocytes, inflammation, and a high rate of apoptosis, leading ultimately to selective outgrowth of hepatocytes that no longer expressed or had lost the transgene, as well as to HCC.^{119,138} In contrast to these mice, transgenic mice expressing the entire viral genome from birth do not develop either chronic liver disease or HCC, though antibody to HBsAg is sometimes found in the serum. HBV is constitutively produced in hepatocytes of these mice from a greater than unit length transgene that includes EN1 and EN2 and the preC/C promoter at the 5' end, and extends through the HBV polyadenylation signal at the 3' end²³² (Fig. 68.6). Most hepatocytes in mice express viral proteins, but only centrilobular hepatocytes (i.e., located near the central vein) produce enough core antigen to assemble functional DNA replication complexes.²³² Virus is released from these cells but for unknown reasons, CCC DNA is not formed unless the mice are also deficient for HNF1 α .⁵⁷²

Transgenic mice have been extensively used to examine how the immune system might clear an HBV infection. This work has provided convincing evidence that replicating viral

DNA, viral proteins, and mRNAs can be cleared rapidly from the mouse liver by antiviral cytokines.^{228,230,760} Indeed, when these mice were injected with CTLs reactive to HBsAg, DNA replication intermediates were nearly gone within 24 hours, possibly through a block in assembly and proteasome-dependent degradation.^{230,583}

The rapidity with which replicative intermediates disappear from the liver of the transgenic mice following cytokine induction does not have an evident parallel in the resolution of transient hepadnavirus infections. Nonetheless, findings with the transgenic mice highlight and possibly illuminate a critical issue in the resolution of HBV infections. Following recovery from a transient infection, how is it that the liver is populated by hepatocytes, or the progeny of hepatocytes, that at one time had been infected⁶⁷⁰?

Chimeric Mice

About 20 years ago, Brinster and colleagues created transgenic mice that **express the serine protease urokinase-type plasminogen activator (uPA) in hepatocytes beginning around the time of birth.**⁶⁰² More than half die with intrahepatic bleeding and those that survive either lose or turn off uPA expression within a subpopulation of hepatocytes that then repopulate the liver. Syngeneic hepatocytes, or in a severe combined immunodeficiency (SCID) background, xenogeneic (rat) hepatocytes, inoculated within a week or two of birth, also expanded to repopulate the liver.^{577,578} These early observations suggested that hepatocyte repopulation might also be achieved with human or woodchuck hepatocytes. Mouse livers repopulated with human hepatocytes were shown to be susceptible to HBV¹⁴⁴ and HCV,⁴⁵⁹ and livers repopulated with woodchuck hepatocytes to WHV.⁵⁴¹ An advantage of chimeric mice is the long-term maintenance of transplanted hepatocytes, particularly human hepatocytes. Utilization of this system has been limited because of the technical challenge of acquiring and transplanting human hepatocytes, which is done by injection of hepatocytes into the spleen, from where they migrate to the liver.⁵⁷⁷

In spite of these difficulties, several studies have relied on this model. For example, the requirement for HBx in establishing viremia has been reproduced with the chimeric mouse model.⁷²³ Hence, it can be concluded that X is required for the HBV life cycle even in the absence of a functional immune system. The model has also been useful for studies on the dynamics of HBV infections with genotype G, which is dependent on co-infection with another genotype, commonly genotype A.⁶⁶⁹ Finally, experiments with uPA/SCID mice demonstrated that prolonged HBV replication in the absence of an adaptive immune response can induce pathology similar to fibrosing cholestatic hepatitis observed in immunosuppressed carriers.⁴⁶⁰

Hydrodynamic Infection

A number of years ago, efficient transfection of the liver by DNA or RNA was demonstrated using hydrodynamic injection, which involves inoculation of a hypotonic solution of RNA or DNA via the tail vein.^{93,406} This has been used successfully to establish transient expression of HBV in mouse liver⁷⁸⁰ and to study effectors of virus clearance in this model system (e.g., 781).

Tupaia

The search for a small mammal susceptible to HBV infection led to the discovery that tree shrews (*Tupaia belangeri chinensis*)

can be experimentally infected with HBV.⁷⁷⁷ Similar to acute, self-limited hepatitis B in humans, HBsAg was rapidly cleared from the serum of Tupaia, followed by seroconversion to anti-HBe and anti-HBs.⁷⁴⁴ Moreover, primary hepatocytes isolated from livers of Tupaia are susceptible to HBV infections.^{329,744} The model is useful for investigations on receptor-mediated uptake of HBV (i.e., 216).^{64,219,379} Primary Tupaia hepatocytes were also used for the construction of chimeric mouse livers that could be infected with HBV.^{146,419} Finally, Tupaia were used for studies on the pathogenesis of clinical HBV isolates from patients with fulminant hepatitis.³⁰ These studies raised the possibility that in some cases the virus is directly cytotoxic.

HEPATOCELLULAR CARCINOMA

Epidemiology

About 5 years after the discovery of HBV, Sherlock and colleagues looked for a link between HBV infection and HCC.⁶²⁹ In a cohort of 17 chronically infected males, five presented with HCC. Definitive support for the hypothesis that HBV plays a primary role in the development of HCC came from epidemiologic studies,^{450,560} and particularly from a prospective study by Beasley and colleagues, who followed more than 22,000 Taiwanese men.³¹ The relative lifetime risk for HBsAg-positive males was found to be about 20 compared to uninfected individuals.¹⁷⁹ As mentioned before, the strongest correlation between chronic hepadnavirus infection and HCC was found in WHV-infected woodchucks: almost every animal develops liver cancer within 2 to 3 years postinfection.^{338,677} In humans, liver cancer usually develops after several decades of infection, and is often associated with cirrhosis of the liver. Consistent with the distribution of chronic HBV infections around the globe, HCC is one of the two or three most common malignant neoplasms in people living in China, Taiwan, and southeast Asia, as well as in sub-Saharan Africa.

The realization that HBV is a major carcinogen has spurred intense efforts to unravel the mechanism responsible for the development of HCC. The details of this process are still not understood; there is still uncertainty about the cells from which HCCs arise. The vast majority of tumors contain integrated HBV DNA and, since hepatocytes are the only liver cells clearly susceptible to HBV, it is assumed that most tumors arise by dedifferentiation of mature hepatocytes. This also seems reasonable since hepatocytes constitute a mostly self-renewing population of long-lived cells ($t_{1/2}$ of 6 months or more) that can undergo extensive proliferation to maintain liver mass during periods of chronic or acute hepatocyte destruction. It is also possible that some tumors arise from undifferentiated progenitor cells present in the liver. Present findings are consistent with the concept that the majority of tumors arise from hepatocytes.

In any case, the field has been driven by two hypotheses, one positing a direct effect of the virus in cancer development, the other predicting that HCC formation is a consequence of persistent liver injury caused by the immune response against infected hepatocytes, attributing an indirect role to the virus. In practice, both may contribute to HCC. The former hypothesis appears dependent on the assumption

that HCCs arise from hepatocytes, whereas the latter does not require this assumption.

Viral Factors in HCC

Evidence for a direct role of HBV in human HCC was fueled by the observation that DNA from HCC contained integrated HBV DNA and that tumors were clonal with respect to the viral integration site.¹⁷⁷ This discovery was consistent with a model of insertional mutagenesis found by retrovirologists, in which activation of proto-oncogenes was caused by nearby provirus integration.^{257,532} However, efforts to identify proto-oncogenes adjacent to integrated HBV DNA did not yield clear candidates,⁴⁷⁶ save for a few isolated cases, in which integration sites were found adjacent to or within coding regions of candidate proto-oncogenes including cyclin A, *erb-A*, or retinoic acid receptor beta.^{155,156,748} It is still possible, though unproven, that HBV DNA alters the expression of genes that are distant from the integration site,⁴⁷⁶ perhaps by altering the structure of chromosomes.^{71,628}

Similar investigations of tumors from WHV-infected woodchucks revealed very different results. The majority of these HCCs overexpress N-myc2, a functional pseudogene of N-myc1^{195,567} that is not normally expressed in the liver.^{195,252,296} C-myc and N-myc1 are more rarely overexpressed in woodchuck HCCs. N-myc1 or C-myc overexpression in woodchuck HCCs is typically associated with nearby integration of WHV DNA, while overexpression of N-myc2 may be due either to nearby integration^{195,252} or to integration in the distal *b3n*^{69,70} or *win*¹⁹⁴ loci.

The majority of ground squirrel HCCs overexpress C-myc.^{252,714} However, C-myc overexpression in the ground squirrel does not correlate with nearby integration of GSHV DNA, though it sometimes correlates with copy number amplification of the C-myc locus. Interestingly, the pattern of DNA integration and myc activation in HCCs that arise in woodchucks infected with GSHV is more typical of that seen in ground squirrels infected with GSHV. This suggests that N-myc activation in WHV-infected woodchucks characterizes WHV infections rather than hepadnavirus infections of the woodchuck *per se*. Transcriptional activation of N-myc and C-Myc have not been reported to characterize human HCCs, suggesting that myc activation may play a more central role in rodent than primate HCCs.⁷¹⁴ However, this does not preclude the possibility that genes regulated by myc play a central role in human HCC.³¹⁵

Alternative models, consistent with a direct role of HBV in human HCC, posit that one or several viral gene products are oncogenic. Although the long latency period observed for HCC development indicates that HBV gene products cannot transform hepatocytes in a single hit event, the hypothesis gained momentum with the discovery that transgenic mice expressing HBx developed HCC.³²⁴ The success of this model depended on the selection of the mouse strain, CD1, known to develop spontaneous hepatomas at an increased rate compared to other mouse strains, and high expression levels of the transgene that are not observed during natural infections.³³² It thus appears that X promotes, but does not necessarily initiate, carcinogenesis. In agreement with this notion, an HBx transgene did not promote HCC in another genetic background but, interestingly, these mice were more susceptible to HCC induction by diethylnitrosamine (DEN) than nontransgenic

controls,⁶⁴³ which was subsequently attributed to increased proliferation of altered hepatocytes in the absence of elevated host gene mutation rates.⁴²⁵ In addition, an HBx transgene accelerated development of HCC in C-myc transgenic mice.⁶⁹⁷ Moreover, many cell-culture studies have demonstrated effects of HBx on the cell cycle (e.g., 37,619,713) and on cell viability (e.g., 35,382,404). Conflicting results emerged from these studies, some suggesting that HBx activates cell proliferation and others suggesting that it is cytostatic, or even induces apoptosis (reviewed in 57). Therefore, it must be concluded that the outcome of experiments with HBx are strongly influenced by the selection of cell lines and other experimental conditions.

Nevertheless, HBx may contribute to a multistep hepatocyte transformation process by activating certain signal transduction pathways via its capacity to transactivate at least some viral and host genes or by binding to host proteins, as discussed earlier, such as the DNA repair protein DDB1 or even the proteasome subunit XAPC7, or p53.^{174,184,282,375} It is important, in this regard, to note that HBx is not always expressed in HCCs,⁶⁶⁸ implying that it may not be needed to maintain the transformed state. In addition, subsequent data suggested that the role of HBV gene products in carcinogenesis may be more complex: mice transgenic for the entire viral genome exhibit an increased sensitivity to DEN-mediated HCC that is not dependent on HBx expression.⁸⁰⁵ Consistent with the latter observations, other studies described below suggested that viral envelope proteins are oncogenic. In summary, despite a wealth of information about biological activities of HBx, it has so far not been possible to obtain proof for a direct role of this protein in HCC development.

The discovery of the transactivation function of truncated M envelope proteins also supported a viral oncogene hypothesis (i.e., 609). It should be noted that truncated M proteins are not produced by wild-type HBV. Overexpression of the truncated M protein, with the help of the albumin promoter in transgenic mice, activated the c-Raf/Erk2 signal transduction pathway and in turn increased hepatocyte proliferation.²⁶² These mice developed very small liver tumors by 1 to 2 years of age. Whether these and other observations with model systems bear any relevance to HCC development in humans remains a matter of debate. Interestingly, Su and colleagues have suggested that L protein mutants are responsible for development of a class of preneoplastic lesions consisting of ground-glass hepatocytes (see Cellular Factors in HCC section).⁶⁶⁷ In addition, the intact L protein also has been shown to transactivate viral and host genes.^{190,287,661,773}

Cellular Factors in HCC

Models explaining HCC development in HBV patients entirely via indirect mechanisms take into consideration a hallmark of HBV infections, death, and compensatory regeneration of hepatocytes. Hepatocytes, as noted earlier, constitute a mostly self-renewing population except in conditions of severe liver injury. Progenitor cell proliferation may also be seen late in infection, especially in tumor-bearing and cirrhotic livers. While hepatocyte death and compensatory proliferation to maintain liver mass process are inconsequential on a sporadic basis, this liver injury can cause substantial fibrosis and cirrhosis of the liver under persistent conditions such as those observed in chronic hepatitis B. It is noteworthy that alcohol abuse, storage diseases, and chronic HCV infections have the

same effects, and all are risk factors for HCC. That is, independent of the cause, chronic liver disease is associated with an increased risk of HCC.

The importance of chronic liver injury in HCC has been documented in many studies with mouse models. For instance, transgenic mice expressing levels of the HBV L-protein that are toxic to hepatocytes developed HCC.¹¹⁹ It was suggested that a contributing factor in emergence of HCC in this model was free radicals generated by the large number of macrophages activated in response to the high rate of apoptosis, leading to extensive hepatocyte DNA damage. The idea that oxidative DNA damage was occurring was supported by the detection of deoxyguanosine adducts on DNA isolated from the livers of these mice.²⁴⁷ These data support the notion that HCC is not just due to the effects of L overexpression on the hepatocytes, leading to a high level of hepatocyte death and compensatory proliferation, but also to hepatocyte DNA damage attributable to free radical formation by activated macrophages.⁴³⁹

In a perhaps more relevant model of the events occurring during chronic HBV infections, studies were carried out with transgenic mice expressing low levels of L that did not cause any apparent liver disease. When the immune system of these mice was ablated and replaced with bone marrow cells from syngeneic nontransgenic mice, the resulting immune response led to liver cell injury and HCC.⁴⁸⁰ Moreover, inoculation of the mice with anti-fas ligand antibodies reduced the incidence of HCC, establishing a correlation between the rate of hepatocyte death, compensatory proliferation, and development of HCC.⁴⁸¹ The significance of this relationship for liver cancer has been further emphasized with a novel transgenic mouse model permitting controlled activation of the latent transcription factor NF- κ B.⁴²⁶ Mice deficient for NF- κ B activation in hepatocytes exhibited increased hepatocellular death and compensatory proliferation after DEN treatment compared to normal mice that correlated with an increased rate of HCC development.

In summary, the details of HBV-induced liver cancer remain elusive. We can predict that the combination of alterations in hepatocyte physiology caused on one side by viral gene expression and on the other by changes in the micro-environment of hepatocytes due to inflammation results in the proliferation and eventual transformation of hepatocytes. Viral mechanisms that could contribute to hepatocyte transformation include changes in gene expression caused by HBx, truncated M (or L), and integrated HBV DNA, along with inhibition of DNA repair pathways. Cellular mechanisms include hepatocyte killing by CTLs, induction of DNA damage via reactive oxygen (and nitrogen) radicals produced by macrophages, and expression of cytokines that in conjunction with viral gene expression provide a proliferative stimulus to hepatocytes.

PERSPECTIVE

HBV biology is multifaceted and touches on many areas in the basic and clinical sciences. Among them are liver biology, immunology, virology, and antiviral therapy. During the past three decades we have witnessed major progress in all areas. Investigations on viral DNA replication have uncovered the mechanism for HBV persistence in the infected liver, which is based on continuous rounds of CCC DNA amplification. Studies in animal models have provided insights into the

course of natural infections and into the process of viral clearance. The revelation that clearance depends on a strong CTC response that can eliminate infected hepatocytes explains why current nucleoside-based antiviral therapies can attenuate, but not cure, chronic HBV infections.

In spite of great progress, many gaps in knowledge remain to be filled. For instance, the receptors for hepadnavirus entry into hepatocytes need to be further investigated. The mechanisms for the disassembly of viral capsids, delivery of the genome into the cell nucleus, and formations of CCC DNA need to be clarified. Although a wealth of new information about the possible function of the X protein has accumulated, we still do not know how this small polypeptide regulates viral transcription and replication in hepatocytes during the course of an infection. For the development of antiviral therapies that can cure infections, it will be imperative to gain a better understanding of the immune response against HBV and the possibility of augmenting this response to cure chronic infections. Moreover, the role of cytokines in the resolution of acute infections needs to be investigated. Although CCC DNA does not appear to be a target for the action of cytokines, do they protect regenerated hepatocytes from *de novo* infection? If so, it would explain why infected and uninfected hepatocytes can coexist during the clearance phase. Finally, there are large gaps in our understanding of the role of HBV in hepatocarcinogenesis, the major burden associated with chronic HBV infections. Does the virus play a secondary role (i.e., by causing an increase in hepatocyte death and compensatory proliferation) or does it act as a tumor promoter in a multistep transformation process, as has been documented for colon cancer? Or does HCC in HBV carriers arise from hepatocyte progenitor cells or from differentiated hepatocytes? These and other questions will have to be addressed to complete the picture of HBV biology that has come only partially into focus over the past 30 years.

Clinical Features of Acute Hepatitis D

HISTORY

In the mid 1970s, Mario Rizzetto, a gastroenterologist in Turin, Italy, detected a previously unrecognized nuclear antigen in hepatocytes of patients with chronic type B hepatitis. The antigen resembled hepatitis B core antigen (HBcAg) in its association with hepatitis B virus (HBV) infection, although it rarely coexisted with HBcAg (Fig. 69.1). The antigen was initially interpreted as a novel hepatitis B–specific antigen; it was called *delta antigen* (HDAg) and its antibody, *antidelta*.¹³⁵ By 1980, transmission experiments in chimpanzees confirmed that HDAg was a component of a transmissible pathogen that was defective and required co-infection with HBV for its replication.¹³⁶ A radioimmunoassay for antidelta was developed¹³⁹ and showed a high prevalence of antidelta among hemophiliacs and drug users.¹³⁸ Hepatitis associated with HDAg was found to be highly endemic in Italy, especially in the south. By the early 1980s, HDAg and a small RNA were shown to be internal components of a virus-like particle enveloped with hepatitis B surface antigens (HBsAg), the envelope proteins of HBV.¹³⁷ The virus-like delta agent was shown to be associated with the most severe forms of acute and chronic hepatitis in many HBsAg-positive patients.¹⁶⁰ Thus, in some cases, severe disease thought to be caused by HBV was actually the result of concurrent infection with the delta agent. By 1983, evidence for infection with the delta agent had been found on every populated continent.¹³⁴ A year later, in Venezuela, it was found to be the cause of severe hepatitis among indigenous populations not frequently exposed to blood. Subsequently, its importance in South America was extended to include etiologic associations with traditionally severe hepatitis in Colombia (hepatitis de Sierra Nevada de Santa Marta) and Brazil (Labrea black fever), as well as severe hepatitis in Peru and indigenous populations of Ecuador.¹⁰⁵ By 1983, the delta agent was considered sufficiently unique and medically important to be designated a distinct hepatitis virus—hepatitis delta virus (HDV)—and the disease it caused was designated delta or type D hepatitis. Cloning and sequencing of the HDV genome in 1986 confirmed its uniqueness among animal viruses.¹⁸⁰ Other advances in the

FIGURE 69.1. Immunofluorescent staining of a liver biopsy from a hepatitis D virus-infected patient. Hepatitis B virus core antigen (red) is present mainly in the cytoplasm, whereas delta antigen (green) is mainly in the nuclei of hepatocytes, although only rarely coexisting with core. (Courtesy of Dr. Mario Rizzetto.)

molecular biology of HDV have revealed novel pathways; these and the frequently devastating consequences of HDV infection drive further research on this cause of acute and chronic liver disease, despite its diminishing medical importance, in part because of the success of vaccination programs against hepatitis B.⁶⁶ Thus, a chance observation by an inquisitive gastroenterologist resulted in the discovery of one of the most interesting and unusual of human pathogens.

INFECTIOUS AGENT

Classification

HDV is the only member of its own separate genus: *Deltavirus*.⁸⁹

Virion Structure

Figure 69.2 is an image of partially purified HDV particles obtained by electron microscopy (EM) after negative staining.⁷⁵ Particles are roughly spherical and somewhat heterogeneous in size (36 ± 4 nm in diameter).^{75,78} No cryo-EM images or reconstructions are yet available.

Figure 69.3 includes a representation of the HBV envelope proteins L, M, and S. They share a C-terminus, and about 50% of each undergoes site-specific, N-linked glycosylation. In HBV-infected cells, they are used to assemble HBV DNA-containing infectious particles. Also produced is a great excess of empty subviral particles (SVPs), typically 25 nm diameter spheres and 22 nm diameter filaments (as also seen in Fig. 69.2). When HDV genome replication is occurring in such a cell, the HDV RNA-containing particles can be assembled. Such particles will or will not be infectious depending on the presence of the HBV L protein. Within HDV RNA-containing particles is a nucleocapsid: a ribonucleoprotein complex of genomic RNA and 70 to 220 copies of HDAg. By extrapolation from HBV studies, the lipid-containing envelope of HDV contains about 100 copies of the HBV envelope proteins L, M, and S.

FIGURE 69.2. Electron microscope examination of assembled hepatitis D virus (HDV). Virus was assembled in Huh7 cells transfected with one plasmid to initiate HDV genome replication and another to express the three envelope proteins of hepatitis B virus (HBV). Thus, there are no infectious HBV particles present. Particles were affinity purified and negatively stained for electron microscopy. HDV particles ranged from 36 ± 4 nm diameter. However, still present are subviral particles: 25 nm diameter spheres and 22 nm diameter filaments. (Adapted from Gudima S, He Y, Meier A, et al. Assembly of hepatitis delta virus: particle characterization, including the ability to infect primary human hepatocytes. *J Virol* 2007;81:3608–3617.)

Genome Structure and Organization

As indicated in Figure 69.4, the RNA genome is a single-stranded RNA with a circular conformation that can fold on itself to form an unbranched rod-like structure with about 74% base pairing.^{92,180} Most full-length HDV sequences are in the range of 1,672 to 1,697 nucleotides.¹⁴² During replication, genomic RNA increases to around 300,000 copies per cell.³⁹ Also detected are fivefold lower amounts of an exact complementary RNA, the antigenome. This RNA encodes the sole viral protein, HDAg. Thus, the HDV genome is considered as negative stranded.

Both genome and antigenome contain a ribozyme. *In vitro*, these ribozymes, in the presence of divalent metal ions, cleave at a specific site via a trans-esterification to produce a 5'-OH and 2', 3'-cyclic monophosphate.^{60,93} The cleavage sites are at the 5'-edge of 85-nucleotide ribozyme domains. Crystal structures have been reported for these domains both before and after cleavage.^{61,88} Comparison of pre- and post-cleavage states reveals a conformational switch and details of the catalytic mechanism. Recently, these structures have been

FIGURE 69.3. Hepatitis B virus (HBV) envelope proteins and particle assembly. At top are the three envelope proteins of HBV—L, M, and S—which share a common C-terminus, with four transmembrane domains (I–IV). The presence or absence of the N-linked carbohydrate chain leads to two different sizes, as indicated by electrophoretic mobility. M has a unique domain pre-S2 relative to S. Similarly, L has a unique domain pre-S1, relative to M. As indicated at bottom, the serum from HBV-infected individuals contains the infectious DNA-containing HBV as well as empty subviral particles, 25 nm diameter spheres, and 22 nm diameter filaments. The serum of an individual infected with hepatitis D virus (HDV) also contains the infectious and noninfectious forms of HDV. Although delta antigen (green) and genomic HDV RNA can be assembled using only the HBV S protein, the particles are noninfectious, because HDV, like HBV, requires the pre-S1 domain of L to be infectious. (Adapted from an unpublished figure provided by Dr. Stephan Urban.)

used in genome-wide searches for HDV-like ribozymes. Many have been found and confirmed as being expressed as RNAs and of having ribozyme activity.¹⁸³ Such information may assist in understanding the origin of HDV.¹⁶⁷

Stages of Replication

Attachment and Entry

The only natural susceptible cells are hepatocytes. HDV will infect cultures of primary human hepatocytes (PHHs)⁷⁵ and the HepaRG cell line.^{74,164,176} Attachment is via cell surface glycosaminoglycans^{100,154} and is increased more than 15-fold by 4% to 5% polyethylene glycol.^{8,75,164} After attachment, virus entry is relatively slow.^{171,176} For example, after 3 hours of exposure of PHH to HDV, more than 50% of the virus is still on the cell surface and susceptible to entry inhibitors, such as a peptide corresponding to part of the pre-S1 domain at the N-terminus of HBV L.¹⁵⁵ Antibodies to this region can block infectivity.¹⁷⁶ This supports other evidence that HBV L must be present on HDV and HBV for the particles to be infectious. While many host entry receptors have previously been proposed¹⁷⁶ an important new study demonstrates that sodium taurocholate cotransporting peptide is a functional receptor for both HBV and HDV.^{197a} Although HDV genomic RNA and multiple copies of HDAg are present within virions, there is no evidence for organization into a specific nucleocapsid structure of RNA within a proteinaceous shell. In contrast, RNA might be wrapped around multimers of HDAg.³

Transcription

In the Baltimore classification system,⁶³ the HDV RNA genome is single stranded and of negative polarity. However,

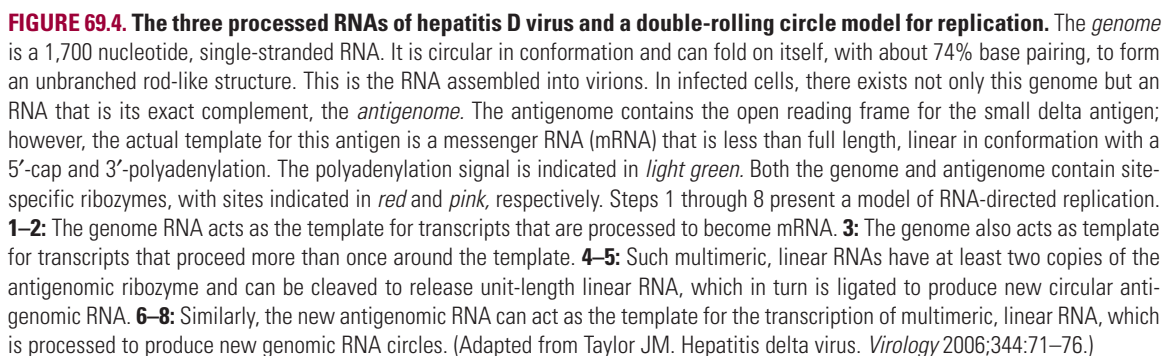

unlike other RNA viruses of negative polarity, HDV does not encode its own RNA polymerase. It somehow redirects the host RNA polymerase II, which normally uses DNA templates, to copy the HDV RNAs.^{72,169} Some studies suggest that replication involves redirection of an additional host polymerase, maybe RNA polymerase I.¹⁷⁴

Translation

The exact complement of the HDV genome, the antigenome, contains the coding region for HDAg. However, translation is considered to be from a third and less abundant RNA that has features of a typical host messenger RNA (mRNA). It is linear, with a 5'-cap and a 3'-polyadenylation (see Fig. 69.4).

There are actually two forms of HDAg translated. First, S-HDAg is typically 195 amino acids in length. It is essential for the accumulation of HDV RNAs during replication.³⁷ Five reasons, some or all of which may be correct, have been proposed to explain the basis for this essentiality.¹⁷⁰ S-HDAg is too small to be a polymerase; however, some studies suggest that it might help to redirect a host polymerase in RNA-directed transcription.¹⁹⁶

During replication, there is posttranscriptional RNA editing of HDV RNA by a class of enzymes referred to as ADAR, or adenosine deaminases acting on RNA. An important and specific target is on antigenomic RNA at what corresponds to the middle of the amber termination codon UAG for S-HDAg.²⁵ Targeting to this site involves the rod-like folding of the RNA. Deamination to inosine leads to mis-transcription so that mRNAs arise with UGG that codes for tryptophan and allows translation of a 19 amino acid longer form of HDAg

S-HDag and L-HDag are highly basic proteins with electrophoretic mobilities of 24 and 27 kA, respectively.^{10,13} They share 195 amino acids of N-terminal sequence and, as

represented in Figure 69.5, have three common features.^{10,13} First, near the N-terminus is a domain essential for the formation of dimers. A crystal structure of this region indicates an antiparallel coiled-coil interaction.²⁰² Second, a bipartite domain facilitates nuclear localization,^{36,194} although just one part is sufficient to transport a fusion protein.⁴ Finally, a bipartite domain with arginine-rich motifs allows HDag to bind to viral RNAs. Early studies *in vitro* indicated specific recognition of the rod-like structures of genomic and antigenome RNA,³⁸ whereas recent studies find no specificity for binding to RNA

versus DNA, single- versus double stranded, relative to rod-like RNAs.³

HDAg can undergo posttranslational modifications: serine phosphorylation, arginine methylation, lysine acetylation, and lysine sumoylation.^{82,175} Some of these sites have been mapped hoping to determine whether the modifications confer ability to contribute to one or more aspects of viral RNA transcription and accumulation.¹⁷⁵ A concern for such implications is that the extent of such modifications at a particular site can be low.

Attempts have been made without success to determine a structure for full-length S-HDAg. This failure agrees with other studies that indicate a high level of intrinsic disorder.³ Typical of disordered proteins, HDAg readily forms higher-order multimers *in vitro*.³

Replication of Genomic RNA

Transcription takes place in the nucleus. Nuclei isolated from infected cells can continue transcription of both genomic and antigenomic RNAs in a manner that depends on the functionality of host RNA polymerase II.³¹ Some studies invoke the need for a second host polymerase, possibly polymerase I.¹⁷⁴ S-HDAg might facilitate redirection of the host polymerase(s) or the ability to achieve elongation of transcripts on HDV RNA templates.¹⁹⁵ Binding of S-HDAg to RNA polymerase II has been reported.^{23,196} However, an *in vitro* system achieving reconstitution of HDV RNA-directed transcription, with initiation and extensive elongation of nascent RNA, has yet to be established.

Figure 69.3 is a model of HDV replication adapted from studies of plant viroids.⁶⁵ Viroids have similarities to HDV. Their RNA genomes are single stranded, often circular, often with ribozymes, and with transcription in all cases via redirection of host RNA polymerases.¹⁶⁷ Many viroids redirect a plant RNA polymerase II.⁶⁵ Viroids are smaller than HDV, with genomes of 250 to 400 nucleotides. They do not encode proteins and do not have helper viruses.

The model is referred to as a double-rolling circle because both genomic and antigenomic RNAs are circular templates. Transcription can produce RNAs that are even multiples of the unit-length. These can be processed to unit-length by the genomic and antigenomic ribozymes. Such cleaved RNAs then adopt the rod-like folding to facilitate ligation to make new RNA circles. Ligation may be achieved by reversal of the ribozyme¹⁵⁶ or by action of a host RNA ligase.¹³² The model is modified relative to that used for viroids to allow for the synthesis of HDAg mRNA. This RNA transcript has a unique initiation site and is recognized by the host polyadenylation machinery via a polyadenylation signal sequence. The sites for initiation of multimeric RNAs that go on to be processed genomes and antigenomes have yet to be determined. *In vitro* studies have shown that the ends of the rod-like folding for genomic and antigenomic RNA will bind polymerase II.⁷¹ However, they will also bind polymerase I and polymerase III.⁷³

HDV replication produces millions of HDAg per cell.³⁰ More than 100 host proteins are identified as interactors with HDAg. This includes several subunits of polymerase II and other proteins that are essential for HDV RNA accumulation.²³

Assembly and Release

HBV envelope proteins L, M, and S are used for HDV assembly. In nature, HDV can only be released from a cell that has been co-infected with HBV. It remains to be determined whether there is some specific order for this co-infection—that is, does HDV enter before or after HBV? HBV assembly is highly inefficient, leading to a huge excess (1,000–100,000-fold) of empty spheres and filaments (see Figs. 69.2 and 69.4). As represented in Figure 69.6, HDV exploits the excess of these SVPs. HDV nucleocapsids can be assembled using only HBV S, although such particles are not infectious. It is only when relatively small amounts of L are also present that the particles are infectious.¹⁶⁵ M is not essential for assembly or infectivity.¹⁶⁶ Assembly uses envelope proteins already associated with

FIGURE 69.6. Assembly of particles in a cell infected with both hepatitis D virus (HDV) and hepatitis B virus (HBV). Although HDV and HBV are assembled with the same HBV envelope proteins, the mechanisms of assembly and release may be quite different. HDV might assemble like subviral particles, using a secretory pathway. In contrast, HBV seems to use the multivesicular body for release. (Adapted from an unpublished figure provided by Dr. Camille Sureau.)

membranes of the endoplasmic reticulum and/or Golgi apparatus; however, HBV infectious particles and SVPs are assembled and released from cells by distinct pathways with separate host factor requirements.¹⁸² HBV uses the compartment known as the multivesicular body, whereas SVPs are assembled using a secretory pathway. Camille Sureau explains HDV assembly as using a secretory pathway, an interpretation fitting well with observations that HDV titers in the serum of infected patients can reach 10^{11} per milliliter, which is much higher than the maximum of 10^9 observed for HBV.

L-HDAg is essential for HDV assembly. Experimentally, it can be assembled and released by HBV envelope proteins in the absence of HDV RNAs.¹⁴⁷ It is not yet understood how when HDV replication is occurring, that it is only the genomic RNA assembled.

HEPATITIS DELTA VIRUS HETEROGENEITY AND VIRAL GENOTYPES

HDV is characterized by a high degree of genetic heterogeneity. Estimates of the rate of mutation fall between 3×10^{-2} and 3×10^{-3} base substitutions per genome site per year.⁹⁹ HDV circulates within a single infected host as a quasispecies.⁵¹ Eight

distinct HDV genotypes have been proposed⁴⁹ (Fig. 69.7 and eBook supplementary information). The genetic heterogeneity of HDV is not uniformly distributed over the viral genome; the most conserved region is within the ribozymes.¹³⁰ Genotype 1 has a worldwide distribution, whereas the remaining genotypes appear to be more geographically restricted (see Fig. 65.7). Genotypes 2 and 4 are found predominantly in the Far East, and genotype 3 is found exclusively in South America. Genotypes 5 through 8 have been exclusively found in West and Central Africa. In Taiwan, genotypes 1 and 4 overlap, and chimeric forms have been detected in co-infected patients.^{181,192} Such *in vivo* recombination, presumably via a template-switching mechanism,³⁴ is a unique phenomenon for a virus whose replication depends on a host RNA polymerase.

HOST RANGE AND EXPERIMENTAL INFECTION IN ANIMALS

In nature, HDV infection has been found only in humans. The host range for productive replication of HDV is limited to those species that support the replication of a hepadnavirus capable of supplying the essential helper function—the surface antigen envelope. These include the chimpanzee (HBV)¹³⁶ and

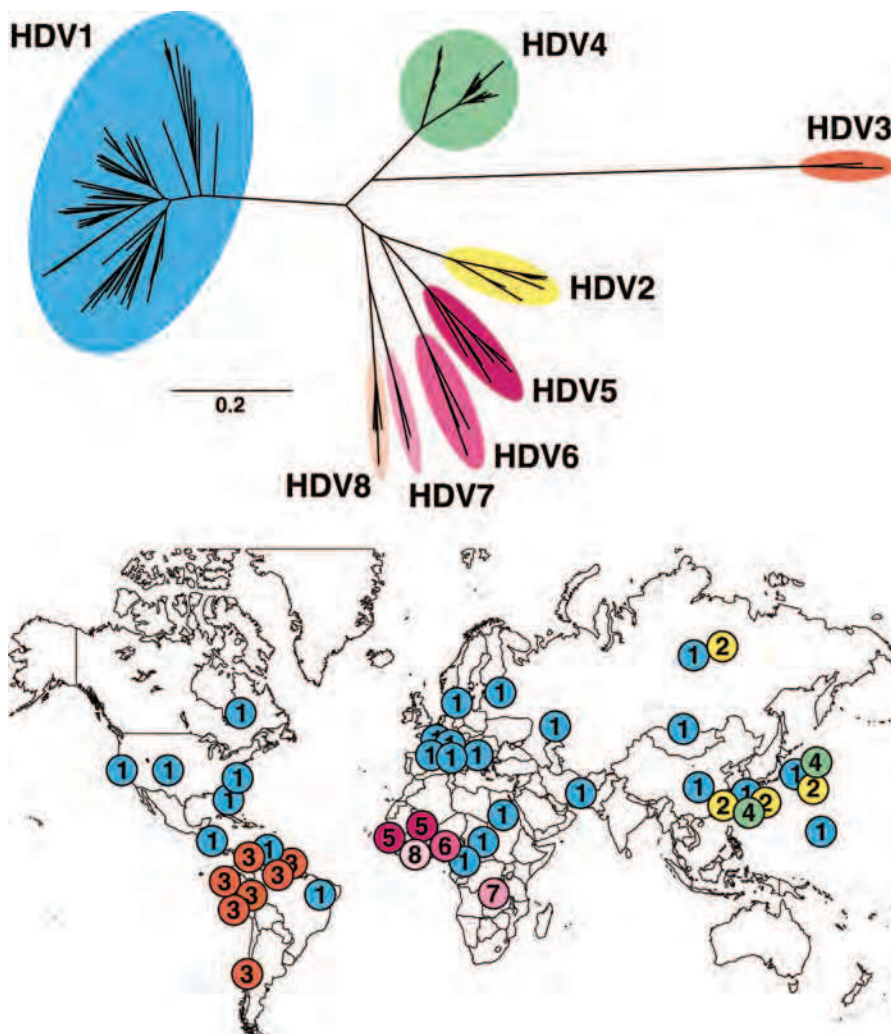

FIGURE 69.7. Geographic distribution of hepatitis delta virus (HDV) genotypes. Bayesian phylogenetic reconstruction based on full-length HDV sequence retrieved from databases (March 2011, $n = 167$). Alignment was performed using Clustal X. MCMC bayesian analyses were conducted in parallel for three million generations using MrBayes until an average standard deviation of split frequencies of 0.025. The first 50% of trees were burn in and the final display obtained with FigTree in the radial option. Selected full-length sequence isolates were kept for clarity. Circles on the map correspond approximately to geographic origin of selected isolates, identified by genotype. The horizontal bar indicates the percentage expected substitution per position. (Courtesy of Dr. Paul Deny).

the eastern woodchuck (woodchuck hepatitis virus [WHV]).¹²⁴ Infection of chimpanzees mimics that of humans, and much of our understanding of HDV infection is based on studies in this experimental model; both co-infection (simultaneous infection with HBV and HDV) and superinfection (infection of an HBsAg-positive subject) have been documented.¹²⁹ Co-infection results in moderately severe hepatitis consisting of a unimodal or bimodal elevation of serum alanine aminotransferase (ALT) activity and associated hepatitis (see eBook supplementary information). Co-infections of HDV and HBV usually result in acute, self-limiting hepatitis D. Superinfection of HBV-carrier chimpanzees with HDV usually results in a more severe acute hepatitis, which progresses to chronicity in about 50% of superinfected animals.¹⁰⁹ The liver appears to be the only organ involved in HDV infection of chimpanzees. Hepatitis D in chimpanzees is generally more severe than other types of human viral hepatitis in this animal model.

HDV of human origin also infects woodchucks (*Marmota monax*) that are infected with WHV, causing acute or chronic hepatitis in a high proportion of animals.¹²⁴ Hepatitis D in woodchucks is similar to that seen in chimpanzees; the liver is the only organ involved. Replication of HDV in woodchucks depends on the presence of replicating WHV and replacing the HBsAg envelope of HBV with the WHV envelope (WHsAg).

Several efforts have been made to develop a mouse model of HDV infection. A limited infection was achieved by intravenous inoculation of HDV or HDV complementary DNA (cDNA) or HDV RNA, resulting in a single round of replication of the HDV genome in hepatocytes.^{33,112} In the absence of a helper hepadnavirus, no release of complete virus and no secondary infection can occur. To develop models that may be more physiologically relevant, mice have been modified to contain human hepatocytes.¹⁴ A high degree of human hepatocyte chimerism (up to 95%) has recently been achieved using *Fab^{-/-} Rag2^{-/-} Il2rg^{-/-}* mice, which were shown to sustain the growth of both HBV and hepatitis C virus (HCV).¹² Efforts to develop transgenic mouse models of HDV RNA replication have been successful, resulting in HDsAg expression in multiple tissues, particularly in skeletal muscle, although no pathologic changes were observed in any tissue, including the liver, supporting the hypothesis that HDV is not directly cytopathic.¹²³ Although these models have expanded the possibilities to study HDV infection, their relevance to pathogenesis remains to be established.

PATHOGENESIS AND PATHOLOGY

Entry Into the Host and Site of Primary Replication

In accordance with the dependence of HDV on HBV, natural infection with HDV follows the same parenteral route of transmission of the helper HBV. In natural and experimental infections, the only infected cell is the hepatocyte. A recent study has demonstrated that sodium taurocholate polypeptide is a functional receptor on hepatocytes for both HBV and HDV.^{197a} If one circumvents the viral entry process by transfection, the HDV genome can replicate in virtually any animal cell. Thus, the restriction of HDV (and HBV) is at the level of virus entry. HDV is assembled in infected hepatocytes and released into the blood. Using the duck hepatitis B virus (DHBV) model, it has

been proposed that the virus first reaches the liver sinusoids, where it is uptaken by liver sinusoidal endothelial cells to be actively transported to the underlying hepatocytes.¹⁸ Whether this model also applies to HDV remains to be established.

Mechanisms of Liver Damage

The pathogenesis of hepatitis D is still poorly understood. HDV is a highly pathogenic virus that causes the most severe forms of acute and chronic viral hepatitis. Controversy exists, however, regarding the relative role played by the direct pathogenic effects of HDV versus immune-mediated liver damage. A direct cytopathic effect of the small form of the delta antigen, S-HDAs, expressed *in vitro* at high levels in the absence of replication of the HDV genome has been reported.⁴³ In other *in vitro* models, replication of the HDV genome was shown to interfere with the ability of transfected cells to expand and form clones¹⁷⁹ and, more recently, to cause cell cycle arrest and cell death.³⁰ These *in vitro* observations are not supported, however, by (a) the presence of intact hepatocytes containing HDAs in human liver biopsies,¹¹⁰ (b) the lack of liver injury documented in liver grafts expressing HDAs in the presence of low levels of HBV replication,¹¹⁹ (c) the lack of liver pathology in a transgenic mouse model expressing both the small and large forms of HDAs,¹²³ and (d) the observation that some HDV-infected cell lines can survive *in vitro* for at least several cell divisions.¹¹ Thus, these data argue against a direct cytopathic effect of HDV and support the notion that *in vivo* damage to infected hepatocytes is immunologically mediated. As with the other hepatitis viruses, peak HDV replication precedes the peak histopathologic changes. Viral replication is often markedly diminished at the time of the peak of pathology when the adaptive humoral and cellular immune responses have begun.

Liver Fibrogenesis and Hepatocarcinogenesis

The mechanisms whereby HDV induces the most rapidly progressive form of liver fibrosis are unknown. L-HDAs may play a role in HDV-related fibrogenesis by regulating transforming growth factor beta (TGF- β)-induced intracellular signaling.⁴² Of note, studies by microarray technology have shown distinct profiles of gene expression in HDV-related cirrhosis compared to that associated with other hepatitis viruses (P. Farci et al, unpublished data).

Although hepatocellular carcinoma (HCC) develops in a proportion of patients with HDV infection, it is still uncertain whether this virus possesses inherent oncogenic properties. Recent data have shown that HDV replication epigenetically enhances the expression of clusterin—a protein that plays a role in tumorigenesis and is highly expressed in HCC—leading to decreased sensitivity to adriamycin.¹⁰¹ Moreover, expression of L-HDAs was shown to increase tumor necrosis factor alpha (TNF- α)-induced NF κ B activation via direct interaction with the transcription factor TRAF2.¹²¹ The relevance of these observations to hepatocarcinogenesis in HDV-infected individuals remains to be established.

IMMUNE RESPONSE

Innate Immunity

The interaction between the virus and the host immune response is key in determining the outcome of viral infections.

Studies of gene expression profiling in weekly liver biopsies of experimentally infected chimpanzees have provided evidence that HBV does not induce expression of intrahepatic genes during entry and expansion, suggesting that it behaves as a stealth virus early in the infection;¹⁸⁸ nevertheless, recovery occurs in more than 90% of cases. By contrast, HCV induces a strong early innate immune response but seems to be resistant to the antiviral effects of the innate immunity, resulting in chronic infection in up to 80% of the infected individuals.¹⁶² Recent studies in chronic HBsAg-positive chimpanzees superinfected with HDV reveal that HDV, like HCV, induces a strong innate immune response, even though the infection in this setting becomes chronic in about 90% of cases (R. H. Purcell, unpublished data). In this respect, *in vitro* data using a hepatoma cell line have documented an inhibitory effect of HDV on interferon alpha (IFN- α)-elicited intracellular signaling, mediated by blockade of Tyk2 activation, resulting in selective impairment of nuclear translocation of STAT1 and STAT2.¹²⁷ Conversely, up-regulation of the interferon-inducible gene *MxA* by L-HDAg, resulting in HBV repression, has been reported in another study.¹⁸⁹ Thus, HDV seems to induce a robust innate response; however, as in HCV, this is ineffective in viral clearance.

Adaptive Immunity

HDV elicits specific antibodies of immunoglobulin G (IgG) and immunoglobulin M (IgM) class against HDAg, which are typically detected during the acute and chronic phase of infection¹⁴⁰ (Fig. 69.8). These antibodies do not have neutralizing activity because they are directed against the HDAg, the only protein encoded by the HDV genome, which is located in the interior of the virion. Because both HBV and HDV share the same envelope, HBsAg, antibodies to HBsAg (anti-HBs) confer protective immunity to both viruses.

The contribution of cell-mediated immune response in the defense against HDV, as well as in the pathogenesis of HDV disease, remains largely undefined.¹⁸⁵ The limited available data suggest that the strength of the host HDAg-specific T-cell response in peripheral blood of patients with chronic hepatitis D correlates with the degree of control of HDV infection.^{83,117} More recently, the frequency of antigen-specific cytotoxic CD4⁺ T cells was found to be higher in patients with HDV infection than in those with HBV or HCV infection.⁷

ROLE OF HEPATITIS B AND D VIRUS GENOTYPES IN PATHOGENESIS

The role of the various HDV and HBV genotypes in the pathogenesis and severity of hepatitis D has been an area of active investigation. Genotype 1, the most prevalent worldwide, has been linked with a broad spectrum of disease severity.¹⁴⁰ Genotypes 2 and 4 have been associated with milder forms of the disease,^{163,191} whereas genotype 3 has been linked with outbreaks of severe and fulminant hepatitis in northern South America.^{26,70,105} Although initially associated almost exclusively with HBV genotype F,²⁷ HDV genotype 3 has since been found in patients with HBV genotypes A and D, although less frequently,⁷⁰ suggesting that HBV genotype F is not essential for the development of fulminant hepatitis D. Further studies are needed to elucidate whether major biological differences exist among HDV genotypes, including the recently described African genotypes, in terms of viral replication, packaging, infectivity, transmissibility, and pathogenicity, as well as the role of the HBV genotypes and the variability of the host immune responses.

FIGURE 69.8. The serologic patterns of type D hepatitis: co-infection and superinfection. **Top:** Coexistent acute hepatitis B and hepatitis D. **Middle:** Acute hepatitis D superimposed on a chronic hepatitis B virus infection. **Bottom:** Acute hepatitis D progressing to chronic hepatitis, superimposed on a chronic hepatitis B virus infection.

LIVER PATHOLOGY

Direct pathologic changes in hepatitis D are limited to the liver—the only organ in which HDV is known to replicate. Histologic changes consist of hepatocellular necrosis and inflammation typical of acute or chronic viral hepatitis. No distinguishing features of the liver histology differentiate hepatitis D from other forms of viral hepatitis, except that the former tends to be more severe and that elements of both acute and chronic hepatitis may coexist if acute HDV infection is superimposed on chronic HBV infection. In acute hepatitis D, inflammatory cells, primarily lymphocytes and Kupffer cells, are prominent in the parenchyma and portal areas. Hepatocytes may be swollen and undergoing eosinophilic necrosis. Pathologic changes are often patchy and focal, except in more severe cases, when confluent, submassive, or massive necrosis is seen. Inflammation and hepatocellular necrosis are also typical of chronic hepatitis D, although inflammation is largely portal, predominantly periportal, with aggregates of lymphocytes and Kupffer cells (Fig. 69.9A). Necrosis of hepatocytes is usually evident, and its distribution is typically periportal. The degree of periportal necrosis (interface hepatitis) is more prominent than in the other forms of chronic viral hepatitis and is often accompanied by active cirrhosis (see Fig. 69.9B). Once cirrhosis is established, HCC may eventually develop in some cases (see Fig. 69.9C). HDAg is commonly detected in the hepatocyte nuclei (see Fig. 69.9D).

A histologic lesion peculiar to infection with HDV genotype 3 in northern South America, especially in the Amazon Basin, is a microvesicular steatosis that gives rise to a characteristic alteration of the hepatocytes (morula cells).¹²⁶ Similar cells, however, have been seen in severe hepatitis D elsewhere, including Africa and Italy.¹⁴⁰ Only nonspecific EM changes have been observed in natural and experimental HDV infections (see eBook supplementary information).

CLINICAL FEATURES AND NATURAL HISTORY

Acute Hepatitis D: Co-infection and Superinfection

Because HDV infection has an absolute requirement for an associated HBV infection, acute disease occurs as one of two patterns, depending on the prior HBsAg status of the HDV-infected subject: co-infection and superinfection. Simultaneous infection of a susceptible individual with HBV and HDV (co-infection pattern) results in both acute type B hepatitis and acute type D hepatitis. The clinical expression of acute hepatitis D acquired by co-infection with HBV may range from mild to severe or even fulminant hepatitis, the most severe form of acute disease, which is a rare sequela of acute viral hepatitis but is approximately ten times more common in hepatitis D than in the other types of viral hepatitis. The mortality rate of fulminant hepatitis was approximately 80% prior to the advent of orthotopic liver transplantation.

Co-infection of HBV and HDV usually results in an acute self-limited hepatitis that is clinically indistinguishable from the typical acute hepatitis B (see eBook supplementary information). The outcome is a complete recovery, as typically seen in acute hepatitis B; in only 2% of cases, it may progress to chronicity.²⁴

HDV infection of an individual chronically infected with HBV (superinfection pattern) causes a generally severe acute hepatitis with a relatively short incubation period that may run to a fulminant course. In this setting, the pre-existing HBsAg status provides the biological background for the full expression of the virulence of HDV. The acute hepatitis in the superinfection pattern is usually marked by an overt clinical illness and jaundice. Clinically, it may present as an exacerbation of a pre-existing chronic hepatitis B leading to liver decompensation or as a new hepatitis in a previously asymptomatic HBsAg carrier. If the HBsAg state is unknown, it may be misdiagnosed as acute

FIGURE 69.9. Histologic stages of hepatitis D. Chronic hepatitis D showing marked periportal (interphase) and lobular inflammatory activity (**A**). Aggregates of Kupffer cells and lymphocytes are seen around hydropic and necrotic hepatocytes. (Hematoxylin and eosin [H&E] $\times 200$). (Courtesy of Dr. Sugantha Govindarajan). During the progression of chronic hepatitis D, active cirrhosis develops in a high proportion of patients (**B**) (H&E $\times 100$). Hepatitis D virus–related cirrhosis is characterized by a marked septal and periseptal inflammation associated with hepatocytolysis. Once cirrhosis has become established, hepatocellular carcinoma may develop in some patients (**C**) (H&E $\times 200$) (Panels B and C courtesy of Dr. David Kleiner). In (**D**), immunoperoxidase staining shows hepatitis delta antigen within the nuclei of hepatocytes (H&E $\times 200$). (Courtesy of Dr. Sugantha Govindarajan; adapted from Farci P. Hepatitis D. In: Dooley JS, Lok ASF, Burroughs AK, et al, eds. *Sherlock's Diseases of the Liver and Biliary System*. 12th ed. Indianapolis: Wiley-Blackwell; 2011:393–405.)

hepatitis B.⁵⁸ Superinfection with HDV is often associated with fulminant hepatitis.

Because the HBsAg state permits the continuous replication of HDV, superinfection of acute hepatitis D leads to chronic hepatitis D in more than 90% of cases.²⁴ A subacute, rapidly progressive form of HDV superinfection has been seen in HBsAg carriers among the Yucpa Indians, an indigenous population of Venezuela.¹²⁶ Such patients often die within 18 months of disease onset.

Chronic Hepatitis D

Chronic viral hepatitis, a frequent sequela of hepatitis D acquired through the superinfection pattern, is associated with the most severe and progressive form of chronic liver disease, often leading to cirrhosis. Unlike other forms of chronic viral hepatitis, chronic hepatitis D is initiated in about half the patients by a clinically apparent acute hepatitis, which likely represents the time of HDV superinfection. The clinical presentation of chronic hepatitis D is variable and shows no distinctive clinical features, except for a higher frequency of splenomegaly. It may be asymptomatic and discovered incidentally, or it can present with general symptoms such as fatigue, malaise, anorexia, and right upper quadrant discomfort, or with the complications of cirrhosis. Typically, patients with chronic hepatitis D exhibit persistently high levels of serum ALT and aspartate aminotransferase (AST), which tend to decrease with the progression of the disease to the end-stage liver cirrhosis. Patients with chronic hepatitis D are usually positive for IgG and IgM antibodies to HDV and show high levels of HDV viremia, although the viral load does not seem to correlate with the severity of the disease.²⁰¹ The production and serum titer of HDV are correlated with the amount of HBsAg in serum in both *in vitro* and *in vivo* studies.¹⁵⁷ Although most chronically HDV-infected patients are positive for antibodies to hepatitis B e-antigen (HBeAg) with little or undetectable HBV DNA levels in serum,¹⁴⁹ a minority of them are HBeAg positive with high levels of HBV DNA replication, a pattern most frequently seen in intravenous drug addicts.¹⁴⁰ The usual suppressive effect of HDV on HBV replication suggests that the liver damage is caused by the ongoing HDV infection and not by the accompanying HBV infection, as further demonstrated by the lack of correlation between HBV replication levels and ALT levels. Chronic hepatitis D can be associated with several autoimmune manifestations, including the presence of autoantibodies against microsomal membranes of the liver and kidney (LKM-3), human thymocytes, and nuclear lamin C.¹¹⁸

In addition to the typical acute and chronic hepatitis D, a third form of HDV infection has been described in the liver transplantation setting. In this unconventional form, defined by some authors as *latent infection*,¹¹⁹ markers of HDV infection are detectable in the absence of markers of HBV infection, suggesting that HDV might replicate at low levels in the absence of the helper function of HBV. However, subsequent analysis with sensitive molecular assays has documented low-level HBV replication coincident with HDV replication, thus reaffirming the dependence of HDV on the HBV helper function and the absence of true latency.¹⁵⁸ Nevertheless, the temporal sequence of HBV and HDV reinfections in transplanted patients remains to be determined.

Natural History

HDV is a highly pathogenic virus that causes the most severe and rapidly progressive form of viral hepatitis at all ages. Studies on the natural history of chronic hepatitis D have shown that cirrhosis develops in 70% to 80% of patients within 5 to 10 years¹⁴¹ and at a younger age compared to hepatitis B–associated cirrhosis.⁵⁹ The risk of developing cirrhosis is about threefold higher in HDV-infected patients compared to those infected with HBV alone.⁵⁹ Once established, HDV-related cirrhosis can be a stable disease compatible with a good quality of life for another decade, although later in the course a high proportion of patients die of liver decompensation or HCC unless they receive liver transplantation.¹⁴⁵ The lack of large prospective studies on the course of chronic hepatitis D makes it difficult to define the proportion of patients who develop each of these long-term complications. Most of the data are inferred from retrospective studies. In two recent longitudinal studies conducted in Italy,^{116,144} liver decompensation—not HCC—was the dominant complication of HDV cirrhosis, developing in 29% to 33% of cirrhotic patients, whereas HCC was observed in 13% to 25%. The estimated annual incidence rates were 2.5% and 2.7% for liver decompensation and 1% to 2.8% for HCC.^{116,144} The association of HDV with HCC has been demonstrated; however, the data on the risk of HCC in HDV-infected patients are not univocal. Whereas in some studies HDV appeared to be a promotion factor of HCC,^{77,178} with a threefold increased risk compared to patients with HBV cirrhosis alone,⁵⁹ in other studies HDV did not appear to increase the risk of HCC over HBV.^{19,44} Recent epidemiological studies in Mongolia, where the incidence of HCC is one of the highest in the world, showed the presence of markers of HBV and HDV infection in 25% of patients with HCC.¹²⁰ A high prevalence of HDV markers (20%) was also documented in patients with HCC in Turkey.¹⁷⁷ Whether HCC is the result of the underlying cirrhosis (a known risk factor for HCC), a direct carcinogenic effect of HDV, or the cumulative carcinogenic effect of HBV and HDV remains to be established.

Although HDV infection is usually associated with severe and progressive liver disease, a few studies have documented a high proportion of individuals with antibodies specific for HDV antigen (anti-HD) without evidence of liver disease.^{5,77} In patients with chronic HDV infection, spontaneous clearance of HBsAg is a rare event, although it may occur either spontaneously^{19,114} or following successful interferon therapy.^{37,116} Clearance of HBsAg is often associated with an improvement of HDV-associated disease, unless it takes place after HDV disease has progressed to advanced stages. Overall, these data suggest that the natural history of chronic hepatitis D varies widely.

The clinical picture of HDV disease worldwide is evolving as a consequence of a changing epidemiologic trend, which has led over the past two decades to a significant decline in the incidence of HDV infection in developed countries, especially in southern Europe.⁶⁶ This reduction has resulted in a dramatic decline in the frequency of new and florid forms of hepatitis D in Europe, with a preponderance of long-standing infections in patients who survived the impact of hepatitis D at the time of the HDV epidemic in the 1980s, who have either advanced cirrhosis or, in a minority, an indolent, nonprogressive disease.¹⁴⁵ Over the past few years, however, new florid HDV cases are on the rise again in western Europe as a

result of immigration from areas of the world where HDV is endemic.^{44,67,97,184}

Interaction of Hepatitis D Virus with Other Hepatitis Viruses

The interaction of HDV with other hepatitis viruses is complex and may lead to different patterns of viral interference. Despite the critical dependence of HDV on HBsAg for its assembly and transmission, a series of studies in chimpanzees¹²⁹ and humans^{79,149,201} have demonstrated that HDV suppresses the replication of HBV. Most HDV-infected patients are anti-HBe positive and have low to undetectable levels of serum HBV DNA, although studies performed with sensitive molecular assays have suggested that serum HBV DNA and HDV RNA levels tend to fluctuate over time in individual patients.^{131,153} By contrast, the serum levels of HBsAg are usually high despite the suppression of HBV DNA and are not significantly different from those that are HBV monoinfected.^{79,201} In a recent study,¹²² the intrahepatic levels of relaxed-circular HBV DNA and covalently closed circular HBV DNA (cccDNA) were shown to be approximately 2-log lower in HDV-infected than in HBV-monoinfected patients, in parallel with approximately 5-log lower levels of serum HBV DNA; however, the concentrations of HBsAg in serum were similar in the two groups, with higher levels of intrahepatic pre-S/SRNA and serum HBsAg amounts per cccDNA molecule in HDV-positive patients, showing that HBV replication was reduced, whereas the synthesis of envelope proteins was not. These results illustrate the “smart” selective mode of HDV-mediated HBV suppression, with maintenance of the capacity to synthesize large amounts of envelope proteins that are necessary for HDV assembly and transmission.

In patients with triple infection with HBV, HCV, and HDV, most reports have documented a suppressive effect of HDV on both HBV and HCV,^{6,85,148} whereas studies from Taiwan have demonstrated a suppressive role of HCV on HBV and HDV.^{102,103} Co-infection with human immunodeficiency virus (HIV) does not seem to influence the natural history of chronic hepatitis D, although the clinical prognosis of hepatitis D in HIV-infected patients is worse when associated with hepatitis C.²⁰ The prevalence of cirrhosis in HIV-infected patients is higher in HBV/HCV/HDV co-infection (67%) compared to HBV/HCV co-infection (42%) or to infection with HBV alone (6%), emphasizing the highly pathogenic effects of HDV.²⁸ In HIV-infected patients, the antibody response to HDV may be more elusive as a consequence of immune suppression, leading to the reappearance of serum HDsAg in some patients.¹⁴³ Also in the HIV setting, HDV was shown to exert a suppressive role on both HBV and HCV.¹⁷

EPIDEMIOLOGY

Age

HDV infects all age groups, although perinatal HDV transmission (with HBV) is not common in regions of the world, such as Asia, where perinatal transmission of HBV is common. Hepatitis D affects children in the Amazon Basin and has occurred among children with hemophilia in industrialized countries, especially before blood was screened for HBV. It also occurs among young adults over most of its geographic distribution

and especially among young users of illicit drugs in industrialized countries.

Morbidity and Mortality

The ratio of clinical to subclinical cases of HDV co-infection and superinfection is unknown; however, the general severity of both forms of infection suggests that most cases are clinically important. The chronicity rate is 2% for co-infection and 90% for superinfection.²⁴ The mortality rate of hepatitis D is 2% to 20%—ten times higher than the rate for hepatitis B, the next most severe type of viral hepatitis.

Epidemics

The epidemiology of HDV, which is principally transmitted by exposure to blood, is not conducive to epidemics in the classic sense. Contamination of lots of clotting factors with HDV, as well as with HBV, HCV, and HIV, in past years was responsible, however, for the high incidence of hepatitis among recipients of these products and the high prevalence of serologic evidence of infection.^{146,172} Epidemics of severe hepatitis D have occurred among drug addicts, with prolonged epidemics leading to high cumulative attack rates. Outbreaks of severe hepatitis D have occurred in various regions of northern South America, especially the Amazon Basin, often involving fragile indigenous Amerind populations, such as the Waorani,¹⁰⁵ in Brazil,⁷⁰ as well as in southeastern Russia,⁶⁴ Mongolia,¹⁷³ and Greenland.¹⁶

Prevalence and Seroepidemiology

Seroprevalence studies of anti-HD in HBsAg-positive individuals have shown a worldwide, but nonuniform, distribution (Fig. 69.10). It has been estimated that 15 million HBsAg carriers are also infected with HDV, although these estimates are inaccurate because seroprevalence studies on blood donors or other healthy groups are not representative of the true prevalence because HDV-infected individuals are more likely to be sick than healthy.¹³³ Areas of high prevalence include the Mediterranean Basin, eastern Europe, the Middle East, central and northern Asia, East and Central Africa, the Amazon Basin, and certain islands of the Pacific. Hepatitis D is less common in eastern Asia, although there are regional exceptions. High-risk populations in industrialized countries include users of illicit parenteral drugs and (formerly) individuals exposed to blood or blood products. Infection with HDV is less frequent than infection with HBV or HIV among sexually promiscuous homosexual and heterosexual groups, suggesting that it is not typically a sexually transmitted disease; however, such transmission does occur, as shown by the high prevalence of HDV among prostitutes.^{47,193}

Over the past two decades, the introduction of universal HBV vaccination programs, the improvement in hygiene and socioeconomic conditions, and campaigns for the prevention of acquired immunodeficiency syndrome (AIDS) have led to a significant decline in the prevalence of HDV in industrialized countries, especially in Europe.¹³³ In Italy, the rate of antibody prevalence to HDV in HBsAg carriers decreased from 24.6% in 1983 to 8.3% in 1997,⁶⁶ and significant declines have been reported in Spain,¹⁰⁸ Turkey,⁴⁸ and Taiwan.⁸⁴ This trend, however, is not generalized, as an increased prevalence of HDV was recently found among injection drug users with chronic HBV infection in some cities, such as Baltimore, Maryland, with a

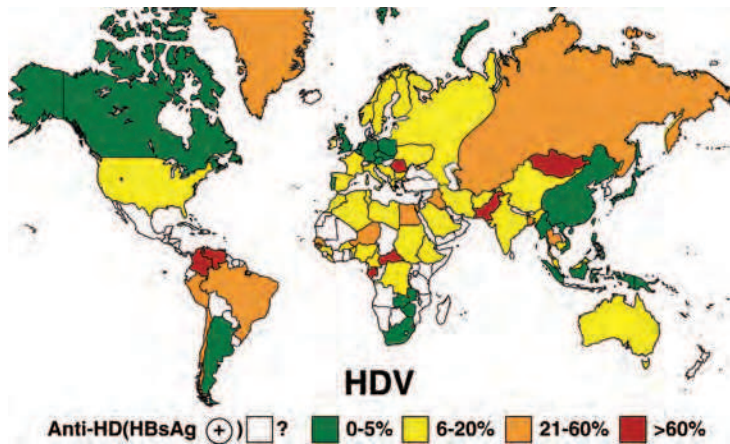

FIGURE 69.10. The worldwide distribution of hepatitis delta virus infection as measured by the prevalence of anti-HD in hepatitis B surface antigen (HBsAg)-positive individuals with acute or chronic hepatitis.

prevalence of 50% in 2005–2006 compared to 29% in 1988–1989.⁹¹ Efforts should be made to expand HBV vaccination coverage to high-risk populations.⁸⁰ In addition, screening of all HBsAg carriers for HDV should be performed and is often neglected, even in the industrialized world.^{44,80}

Despite the overall decline of HDV infection in the industrialized world, immigration from high-endemicity areas is posing a new threat—particularly in Europe, where in the past decade, it has halted the declining trend in the incidence of new cases of HDV infection. In Italy,¹⁶¹ England,⁴⁴ and Germany,¹⁸⁴ the prevalence of anti-HD has not further diminished after 1997, with stable rates ranging from 8% to 14% of HBsAg-positive subjects, mostly confined to immigrants from Romania, Albania, southern and eastern Europe, Africa, and the Middle East. In France, the infection is even increasing in the population of African immigrants.⁹⁷ Thus, the reservoir of HDV in Europe is sustained by two different pools of HDV-infected individuals: one composed by aging individuals who survived the HDV epidemic in the 1970s and 1980s, and the other by young individuals who migrated to Europe from HDV-endemic areas.¹³³

Along with the decline of HDV in developed countries, new foci of HDV infection have emerged in other regions of the world, such as southeastern Russia,⁶⁴ Okinawa, northern India, and Albania.¹³³ Thus, HDV remains a major public health problem in many developing countries where HBV vaccination has not been implemented. Recently, it has been reported that the levels of HDV endemicity are particularly high in Pakistan, Mongolia, Iran, India, Gabon, Vietnam, Tajikistan, Tunisia, Mauritania, and Turkmenistan.^{1,133}

Immunity

Second cases of hepatitis D have not been reported, suggesting that some form of immunity after acute, self-limiting infection exists; this may involve cellular immune mechanisms. HBV-carrier chimpanzees superinfected with HDV were resistant to rechallenge with HDV 6 months later.¹²⁹ Similar chimpanzees rechallenged 3 to 5 years after initial HDV infection were protected or developed mild transient hepatitis. All of the chimpanzees were anti-HD positive at the time of challenge, although most lacked antibodies to the envelope of HDV (i.e., HBsAg). In some of these chimpanzees, however, HDV might still have been replicating at low levels at the time of rechallenge,¹¹¹ and protection by interference rather than immunity could not be ruled out.

Some experimental evidence in woodchucks suggests that immunity to epitopes of the internal HDAg of HDV modifies the course of HDV infection.⁴⁵ Other studies, however, have failed to demonstrate protection.⁶²

Many viruses have developed mechanisms to subvert one or more functions of the host's innate immune mechanism. One study indicated that HDV replication can interfere with interferon signaling.¹²⁷ The HDV mRNA can be attacked by exogenously provided small interfering RNA (siRNA).³⁵ The genome and antigenome are not susceptible to siRNA, however, nor are they cleaved by the enzyme dicer.^{32,35}

DIAGNOSIS

Differential Diagnosis

Hepatitis D should be considered in individuals who are HBsAg positive or who have evidence of recent HBV infection, especially if they have been exposed to blood or blood products, or if they are members of a high-risk population or have lived in a high-risk environment (see later discussion). Other conditions to be differentiated from hepatitis D include co-infection of hepatitis A virus or HCV with HBV, superinfection of an HBsAg carrier with one of these two viruses, or hepatitis E virus, and exacerbation of chronic HBV infection, with disease recurrence.

Laboratory Diagnosis

Co-infection

The diagnosis of HBV/HDV co-infection is based on the simultaneous presence of serologic markers of primary HBV and HDV infection. The typical serologic course of acute HDV co-infection is shown in Figure 69.8. HBsAg, HBeAg, and HBV DNA appear in serum during the incubation period in a pattern characteristic of acute hepatitis B. Both IgM and IgG antibodies to HBeAg appear coincident with the onset of clinical disease; evidence of active viral replication often disappears by the peak of illness. Antibodies to HBsAg appear later, during convalescence. The diagnosis of acute hepatitis D is made on the basis of serologic and molecular tests for this virus. Antibodies to HDAg (anti-HD) develop late in the acute phase of infection and may be present only transiently and in low titer. Assays for IgM anti-HD⁵⁵ and for virion-associated

HDV RNA^{98,197} or HDAg in serum¹⁵⁹ are the most reliable markers of acute HDV infection in the presence of high-titer IgM anti-HBc. In the co-infection pattern, all markers of viral replication disappear in early convalescence, and IgM anti-HD and even IgG anti-HD disappear within months to years after recovery. Loss of IgM anti-HD confirms the resolution of acute hepatitis D, whereas persistence predicts chronicity.

Superinfection

Superinfection of a chronic HBsAg carrier with HDV usually results in persistent HDV infection. A typical serologic pattern for such hepatitis is shown in Figure 69.8. The absence of IgM anti-HBc distinguishes superinfection from co-infection. HDV viremia becomes detectable during the incubation phase and is followed by the appearance of IgM anti-HD and IgG anti-HD during the acute phase. Markers of HBV replication are usually suppressed during the acute phase and may be difficult to demonstrate without comparison with pre-HDV levels or in subjects who are anti-HBe–positive HBsAg carriers but lack active HBV replication at the time of superinfection. Progression to chronicity is associated with high and persisting levels of IgM and IgG anti-HD. These antibodies persist, as do positive tests for serum virion-associated RNA and intrahepatic HDV RNA and HDAg. In addition to its diagnostic value, testing for IgM anti-HD also provides prognostic information, because its decrease and disappearance predicts impending resolution of chronic HDV disease, either spontaneous or induced by interferon therapy.¹⁵

Persisting viremia is associated with chronic HDV infection.^{159,201} The increasing use of molecular methods, such as polymerase chain reaction (PCR) in its standard or quantitative (real-time) formats, to assess viremia in the laboratory diagnosis of clinical disease¹⁰⁷ has overcome the limitations of serologic detection of HDAg caused by antigen sequestration in immune complexes. Molecular tests are crucial for the early diagnosis of HDV infection, before antibody seroconversion. Quantitative PCR may be particularly useful for monitoring the efficacy of antiviral therapy,^{98,106} as well as for investigating the molecular events during acute and chronic hepatitis D.^{159,197} Because of the genetic heterogeneity of HDV, it is important to select primers from highly conserved regions among the eight major genotypes. Primers derived from the ribozymes—the most conserved regions of the HDV genome—are able to detect HDV RNA from all HDV genotypes.⁹⁸ The HDV genotype can be determined by restriction fragment length polymorphism analysis of PCR-amplification products, by sequencing, or, on liver biopsies, by immunohistochemical staining using genotype-specific antibodies.^{81,159}

TREATMENT

Currently, there is no specific treatment for hepatitis D, which remains one of the most difficult liver diseases to treat. Although several antiviral agents have been tried, the only drug of proven benefit for the treatment of chronic hepatitis D is IFN- α .¹¹⁵ The fact that HDV lacks its own viral polymerase, combined with its unusual replicative cycle and its high pathogenic potential, make this virus a difficult target for antiviral therapy.⁵⁴ Specific HDV inhibitors have not yet been developed, and specific HBV inhibitors have little or no effect on HDV replication because

they do not attain a marked suppression of HBsAg expression. Oral antiviral agents that potently inhibit HBV replication, including lamivudine,^{94,115,190} famciclovir,¹⁹⁸ and adefovir,¹⁸⁶ failed to show any efficacy on HDV viremia or liver disease activity in patients with chronic hepatitis D. Data for other more potent antiviral agents presently used for the treatment of chronic hepatitis B, such as entecavir, telbivudine, and tenofovir, are lacking. Immunomodulators (e.g., steroids, thymosin, levamisole, thymic humoral factor- $\gamma 2$) and other antiviral agents (e.g., acyclovir or ribavirin) were also shown to be ineffective.¹¹⁵

Acute Hepatitis D

There is no evidence for benefit of IFN- α in acute hepatitis D,¹¹⁵ including fulminant hepatitis D.¹⁵² Patients with acute hepatitis D should be closely monitored to allow early detection of progression to fulminant hepatitis, for which liver transplantation remains the only valid therapeutic option.

Chronic Hepatitis D

Interferon Alfa Monotherapy

IFN- α was first employed to treat chronic hepatitis D in the mid 1980s and still remains the only licensed drug for the treatment of this disease. Its efficacy is related to the dose and duration of therapy. The usual regimen is 9 million units three times a week or 5 million units daily by injection for at least 1 year.^{56,68} In a controlled trial in Italy, long-term treatment with a high dose of IFN- α (9 million units three times a week for 12 months) led to ALT normalization in 50% of patients 6 months after cessation of therapy.⁵⁶ The biochemical response correlated with a significant decrease in the level of viremia but not with a loss of HDV RNA as measured by sensitive PCR.⁵⁷ Overall, a 1-year course of standard IFN- α at high doses was associated with only a 10% to 20% chance of sustained HDV clearance (Fig. 69.11) and a 10% chance of HBsAg clearance.^{9,96} Patients co-infected with HIV or HCV respond poorly to IFN- α treatment.^{128,187} The results have been disappointing also in children.^{46,50}

Several strategies have been explored to improve the efficacy of IFN- α , most notably a longer duration of treatment.^{95,199} However, most patients still fail to clear the virus.¹¹⁵ Moreover, these regimens are poorly tolerated. Side effects are common during IFN- α treatment; therefore, continuing medical monitoring is essential for the early detection and management of medical and psychiatric complications.⁶⁸

The rationale for treatment is to alter the natural history of chronic hepatitis D, yet very few studies have investigated the long-term effects of IFN- α treatment. A prospective controlled trial of 36 patients followed for up to 20 years provided evidence that the beneficial effects of IFN- α extend well beyond the termination of therapy.⁵⁷ High doses of IFN- α for 12 months significantly improved the long-term clinical outcome and survival of patients with chronic hepatitis D⁵⁷ (Fig. 69.12A). Reversion of advanced hepatic fibrosis occurred in some patients with an initial diagnosis of active cirrhosis (see Fig. 69.12B,C).

Pegylated Interferon Monotherapy

Following the superior results obtained with pegylated IFN- α (Peg-IFN- α) in chronic hepatitis B and C, the efficacy and safety of Peg-IFN- α was recently evaluated in three small studies in which Peg-IFN- $\alpha 2b$ was given at a dose of 1.5 $\mu\text{g/kg}$ for a period of 12 to 72 months.^{29,52,113} These pilot studies showed a

FIGURE 69.11. Rate of sustained virological response to standard interferon (IFN- α) or pegylated interferon (Peg-IFN- α), alone or in combination with lamivudine (LAM), ribavirin (RBV), or adefovir (ADV), in clinical trials in patients with chronic hepatitis D. Hepatitis D virus RNA was measured in serum using polymerase chain reaction assays with a sensitivity ranging from 10 to 1000 genome copies per milliliter. (Adapted from Farci P. Hepatitis D. In: Dooley JS, Lok ASF, Burroughs AK, et al, eds. *Sherlock's Diseases of the Liver and Biliary System*. 12th ed. Indianapolis: Wiley-Blackwell; 2011:393–405.)

sustained virological response, as measured by a sensitive PCR assay, 6 months after the end of treatment in 17% to 43% of patients with chronic hepatitis D (see Fig. 69.11). Differences in disease duration and liver histology (at baseline) on entry into the trial may explain the different rates of virological response achieved in these small studies. Similar results were recently obtained in the largest randomized trial so far conducted,¹⁸⁶ in which 31 patients received 180 μ g of Peg-IFN- α 2a weekly, leading to a sustained virological response in 31% of patients 6 months after the end of treatment (see Fig. 69.11). Although the number and size of studies with Peg-IFN- α are still limited,

they indicate that in both IFN-naïve patients and in previous nonresponders to standard IFN- α , Peg-IFN- α is well tolerated and more effective than standard IFN- α in chronic hepatitis D. The side effects are similar to those observed with standard IFN- α .

Combination Therapy with Conventional or Pegylated Interferon

A few small-size studies have evaluated the effects of combination therapy with standard IFN- α or Peg-IFN- α (see Fig. 69.11). The addition of ribavirin^{76,87} or lamivudine^{22,200} over

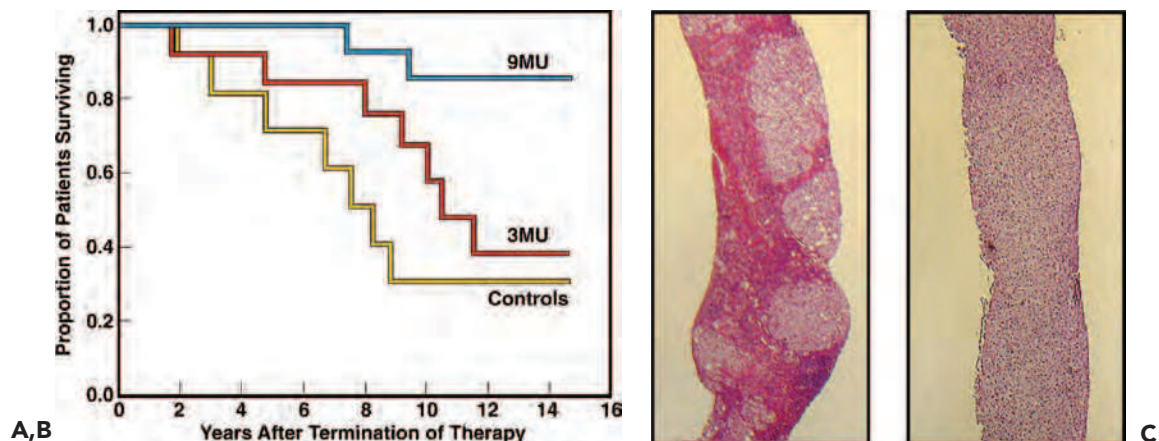

FIGURE 69.12. Interferon treatments. **A:** Cumulative survival among untreated patients and patients treated with 9 or 3 million units of interferon. Survival was significantly longer in the high-dose group than in the low-dose or control groups. No significant difference was seen between the low-dose and control groups. **B, C:** Photomicrographs of liver biopsy specimens obtained from a patient with chronic hepatitis D before (**B**) and 13 years after (**C**) completion of treatment with 9 million units of interferon. The patient had active micronodular cirrhosis before therapy. Inflammatory activity and fibrosis were not detected in the posttreatment biopsy. Similarly, biochemical and clinical evidence of hepatitis was markedly improved following therapy (Adapted from Farci P, Roskams T, Chessa L, et al. Long-term benefit of interferon alpha therapy of chronic hepatitis D: regression of advanced hepatic fibrosis. *Gastroenterology* 2004;126:1740–1749.)

monotherapy with standard IFN- α did not improve the biochemical or the virological response as did combination therapy of Peg-IFN- α with ribavirin¹¹³ or adefovir.¹⁸⁶ Clearance of HBsAg occurred in one case treated with Peg-IFN- α 2b monotherapy²⁹ and in two cases treated with Peg-IFN- α 2a plus adefovir.¹⁸⁶

Predictors of Response to Therapy

There are no clinical or virological features that predict which patients are likely to respond to therapy. However, as documented with standard IFN- α , patients in the early stage of chronic hepatitis D respond better to Peg-IFN- α than those with cirrhosis, underscoring the importance of an early diagnosis and treatment in the management of chronic hepatitis D. Albeit limited in size, recent studies have highlighted the importance of HDV RNA kinetics studies, which provided evidence that a negative PCR for HDV RNA within 6 months of therapy was the best predictor of a sustained virological response to Peg-IFN- α , although in a minority of cases it did not differentiate between responders and relapsers.^{29,52}

Current Recommendations

Peg-IFN- α should be the first choice for the treatment of chronic hepatitis D. It should be offered to all interferon-naïve patients, as well as to previous nonresponders to standard interferon, with well-compensated HDV chronic liver disease, whereas it is contraindicated in patients with advanced, decompensated, liver disease, for which liver transplantation remains the only therapeutic choice. Treatment should be started as soon as the diagnosis is made before cirrhosis develops in order to obtain the best chance of achieving a virological response. Therapy should be continued for at least 1 year before a patient is considered a nonresponder. Monitoring the HDV RNA levels offers clinicians the possibility of tailoring treatment schedules, which will be an important step forward for improving the rate of sustained virological response in chronic hepatitis D.⁵³ The development of commercial assays for the qualitative and quantitative detection of serum HDV RNA is a high priority. Quantification of serum HBsAg levels provides an additional tool for monitoring antiviral therapy.¹⁰⁴ Continuing clinical monitoring is mandatory for the early detection of the side effects induced by interferon treatment.

Future Perspectives for Therapy

Although the results with Peg-IFN- α are better than with standard interferon, the rate of relapse is still high, and a high proportion of patients still do not respond. The reasons for such poor response are unknown, although a recent *in vitro* study suggests that HDV may impair the IFN- α stimulated JAK-STAT signaling pathway.¹²⁷ Treatment of chronic hepatitis D remains unsatisfactory, emphasizing the need for improving the efficacy of interferon therapy as well as for identifying, through innovative molecular approaches, novel agents that target the life cycle of HDV. One of the primary targets is HBsAg, whose production and integrity is critical for the assembly, secretion, and entry of HDV.^{2,86,90,157} Of greater promise is a novel class of prenylation inhibitors, which block an essential step in the assembly of the HDV particles.⁶⁹ Recently, using an experimental transgenic mouse model for HBV that supports high levels of HDV replication, prenylation inhibitors were shown to be highly effective in clearing HDV viremia.¹⁴

Another strategy is the use of synthetic peptides corresponding to part of the HBsAg-L pre-S1 domain, which would inhibit entry of both HBV and HDV presumably through specific interference with a cellular receptor.¹⁵⁵ Additional molecular strategies include the use of ribozymes,⁴¹ antisense oligonucleotides,⁴⁰ and siRNAs³⁵; however, at present, the potential clinical applicability of these approaches appears remote.

Liver Transplantation

Orthotopic liver transplantation represents the only therapeutic choice for treating fulminant hepatitis and end-stage chronic hepatitis D. The results have been better than the disappointing results obtained with chronic HBV infection.¹⁵⁰ Survival after liver transplantation is better in HDV than in HBV or HCV infection. Markers of continuing HDV replication are sometimes found in transplant recipients shortly after transplantation; however, liver disease does not recur unless significant HBV replication occurs.¹⁵⁸ Reinfection is followed by relapse of hepatitis in only 50% of cases, and the hepatitis is usually milder than the original disease. Recurrence of HBV in patients with both HBV and HDV infections is less frequent than in patients with HBV alone and can be prevented by the continuous administration of anti-HBs immunoglobulins¹⁵¹ and lamivudine.²¹ Following the introduction of anti-HBs immunoglobulin prophylaxis, the risk of reinfection with HDV has dropped to 10% and that of reinfection with HBV to 30%. Furthermore, the addition of lamivudine to anti-HBs immunoglobulins before and after liver transplantation has virtually abolished the risk of HDV reinfection.²¹

PREVENTION AND CONTROL

Situations in which an opportunity exists for repeated exposure to HBV constitute the major risks for co-infection or superinfection with HDV. The current policy of excluding blood donors with serologic markers of HBV infection has markedly diminished the chances of HDV transmission by blood transfusion. Similarly, screening of donors to large plasma pools used for the fractionation of blood products has diminished the risk of HBV or HDV infection from such preparations; however, the inadvertent introduction of a single unit of plasma positive for HDV and HBV could contaminate the whole lot because of the high infectivity titers of these two viruses in blood.¹²⁵ Practices designed to minimize the transmission of HBV, HCV, and HIV among drug addicts will also diminish the transmission of HDV to the extent that they are implemented. Implementation of better hygiene, especially control of weeping skin lesions (thought to be involved in the transmission of HDV in some primitive settings), may help to control the spread of HDV and other blood-borne viruses.

Immunoprophylaxis against HDV is achieved by vaccination against HBV, because HDV uses the envelope protein of HBV and has no detectable unique surface antigens.¹³⁶ Hepatitis B vaccines are highly effective in preventing HDV infection and its sequelae. Public health measures to interdict the transmission of blood-borne pathogens, combined with aggressive HBV vaccination programs at the national level, offer the best hope for the control of hepatitis D. Some high-risk populations, however, are among the most difficult to reach with such programs. For example, as with other infectious diseases, the

possibility of vaccination against HBV in developing countries is remote, thereby providing through the high circulation of HBV the biological foundation for the spread of HDV, which therefore remains a major cause of morbidity and mortality in developing countries.

PERSPECTIVES

More than 300 million people in the world who are chronically infected with HBV are also at risk of contracting hepatitis D. These HBsAg carriers are refractory to vaccination with current HBsAg vaccines. Therefore, public health control measures depend on strategies that limit exposure to HDV through high-risk behavior. Future opportunities for prevention of HDV transmission to HBV carriers may include the development of HDV-specific vaccines; however, for the most part, limiting the burden of HDV disease will depend on the aggressive pursuit of HBV control. The implementation of universal HBV vaccination in the industrialized world has resulted in a significant decline in the prevalence of HDV, although immigration from endemic areas poses a threat of HDV resurgence. HDV is still endemic in many developing countries. Thus, more challenges need to be faced in the decades ahead to reduce the global impact of HDV infection in developing countries, where there is an urgent need for political interventions to alleviate poverty and underdevelopment.

HDV is unique among animal viruses, and despite advancement in the molecular biology of this virus, many questions remain in understanding its unusual replicative cycle. The tools provided by the postgenomic era are likely to provide a better understanding of the molecular pathogenesis of hepatitis D, including the role of HDV in hepatocarcinogenesis, and the interaction between HDV and HBV in order to identify novel therapeutic agents that target the life cycle of HDV. Finally, the difficulties in eradicating HDV globally should stimulate a more vibrant research in the different aspects of HDV, because this virus still poses many challenges to both virologists and clinicians.

INFECTIOUS AGENT

Hepatitis E was not recognized as a distinct clinical entity until 1980, when sensitive and specific tests for antibody to hepatitis A virus (anti-HAV) were first applied to the study of epidemic water-borne hepatitis in India.^{79,167} Such disease had long been thought to be caused by hepatitis A virus (HAV), based on the epidemiologic and clinical similarities between these epidemics and well-characterized epidemics of hepatitis A occurring elsewhere. However, these epidemics were found not to be hepatitis A.

The first direct experimental evidence for the existence of an additional water-borne hepatitis agent was reported in 1983 by Balayan et al,¹⁶ who described the successful fecal–oral transmission of hepatitis to a volunteer from patients with hepatitis A–like disease in Central Asia. The volunteer developed severe clinical hepatitis 36 days after ingestion of a fecal suspension from the patients. Virus-like particles (VLPs) of 27 to 30 nm in diameter were detected by immuno-electron microscopy (IEM) in the feces collected from the volunteer between 28 and 45 days after exposure. Balayan et al¹⁶ also reported the transmission of hepatitis to cynomolgus monkeys inoculated with the fecal sample and the recovery of VLPs from their feces.

This form of non-A, non-B hepatitis was named epidemic or enterically transmitted non-A, non-B (ENANB) hepatitis, and the agent of this disease was subsequently found to be the

major cause of sporadic hepatitis cases in regions where the epidemic form was known to exist.^{11,81,125} IEM and transmission to primates (see later discussion) remained the only means of studying ENANB hepatitis until 1990, when Reyes et al¹³⁹ succeeded in cloning and sequencing a part of the virus genome. Many complete sequences of the viral genome are now known, and the agent has been renamed hepatitis E virus (HEV).^{137,139}

Classification

Based on genome organization and superficial structural morphology, HEV was initially classified in the family *Caliciviridae*; however, further sequence analyses showed a closer, although distant, relationship to rubella virus, alphaviruses of the *Togaviridae* family, and plant furoviruses.⁸⁵ Therefore, a new family *Hepeviridae* and genus *Hepevirus* were created with HEV as the sole member¹¹¹ (Fig. 70.1). Genotypes differ from each other by 25% or more and have a characteristic geographic distribution. Currently, there are four recognized genotypes of HEV that infect mammals: genotype 1 (Burmese-like Asian strains), genotype 2 (a Mexican and a few South African strains), genotype 3 (animal strains mainly from swine worldwide and from sporadic human cases in industrialized countries), and genotype 4 (swine strains and sporadic human cases in Asia)^{12,110,132} (Table 70.1). Genotypes 1 and 2 infect only humans and nonhuman primates. Genotypes 3 and 4 infect humans and primates as well; however, their main host is swine but have occasionally been isolated from deer and rabbits, and once from a mongoose.^{49,119,127,177} Isolations from other mammals have been reported but not yet confirmed. All four genotypes have the same serotype.^{41,96,136}

An HEV-like virus isolated from chickens exists as three or more genotypes, shares only 50% nucleotide identity with mammalian strains, and has not been assigned to a genus.^{55,58,102,111,128} Similarly, an unclassified virus isolated from rats shares nearly 55% sequence identity with genotypes 1 through 4 and approximately 50% with avian strains.^{65,66} Additional strains undoubtedly will be isolated from other species.

VIRION STRUCTURE

Morphology

HEV is a nonenveloped, spherical particle, approximately 30 to 34 nm in diameter,¹⁶ with an indefinite surface substructure that is slightly less pronounced than that of the Norwalk agent (a calicivirus) but distinguishable from the smooth, featureless surface of HAV (a picornavirus) (Fig. 70.2). On the basis of morphology, however, HEV cannot be reliably distinguished from other “small round viruses” found in feces. Through the

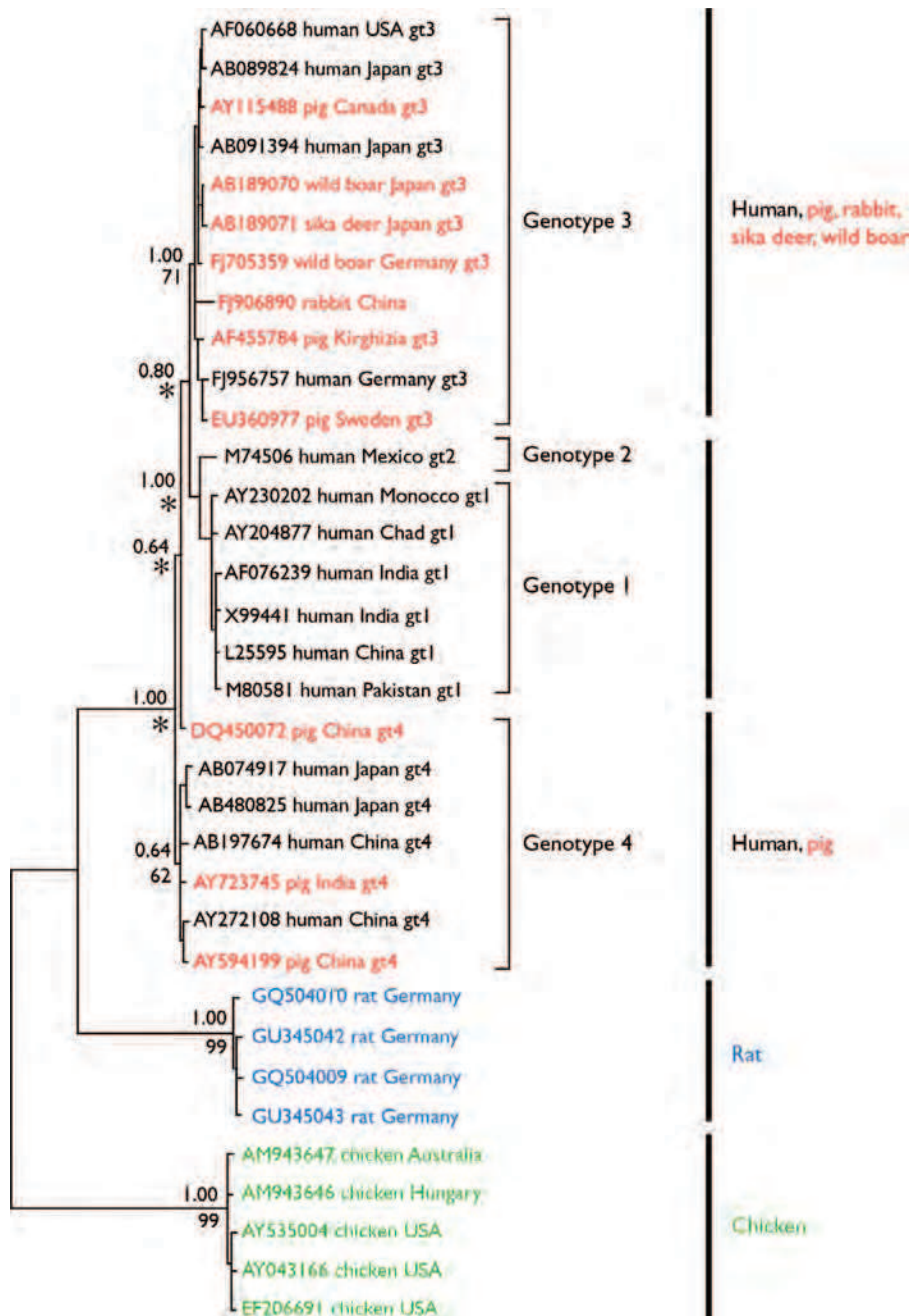

FIGURE 70.1. Phylogenetic tree of hepatitis E virus (HEV) partial nucleotide sequences (1,576 nucleotides). Robustness of nodes is given for Bayesian (above branches) and neighbor-joining (below branches) algorithms. The *asterisk* indicates that neighbor-joining algorithms suggest a closer phylogenetic relationship between genotypes 3 and 4, with genotype 1 basal to these. *Scale bar* indicates phylogenetic distances in nucleotide substitutions per site. The four recognized mammalian genotypes (1–4) are depicted in *black* for human strains and *red* for animal strains; rat HEV sequences, comprising a putative new genus, are shown in *blue*. Avian HEV strains, comprising a putative new genus, are shown in *green*. (Reprinted with permission from John R, Heckel G, Plenge-Bönig A, et al. Novel hepatitis E virus genotype in Norway rats, Germany. *Emerg Infect Dis* 2010;16(9):1452–1455.)

TABLE 70.1 Taxonomy and Host Range

Genotype	Natural host	Other susceptible hosts
1	Human	Nonhuman primates
2	Human	Nonhuman primates
3	Swine	Human, nonhuman primates, deer (sika, red, roe), mongoose
4	Swine	Human, nonhuman primates, cattle (?), sheep (?)
Related to 3	Rabbit	Pig

New Genus?	Chicken	Turkey

techniques of cryo-electron microscopy and crystallography, considerable progress has been made in understanding the structure underlying the morphology of HEV. The principal, if not only, capsid protein of HEV, open reading frame (ORF) 2 (normally 660 amino acids [aa] in length), when truncated (aa 112–608), forms homodimers that can further assemble into 27-nm VLPs with a T = 1 icosahedral symmetry consisting of 30 dimers. ORF2, somewhat less truncated (aa 14–608), can form virus-size (34-nm) VLPs with a T = 3 structure consisting of 90 dimers that mimic the virus and encapsidate RNA (Fig. 70.3). The assembly and morphology of HEV resemble those of other small nonenveloped viruses, especially small plant viruses.^{53,94,169,170}

FIGURE 70.2. Antibody-coated hepatitis E virus particles recovered from the stool of a patient with hepatitis E in Mexico. Immunoelectron microscopy ($\times 223,000$). (Courtesy of D. Bradley.)

Chemistry

The buoyant density of hepatitis E viral antigen or virus particles in feces is reported to be 1.35 g/cm^3 ¹⁷ and 1.39 to 1.40 g/cm^3 ⁴⁴ in cesium chloride (CsCl), 1.29 g/cm^3 in potassium tartrate or glycerol, and 1.27 to 1.28 g/mL in sucrose.^{150,151} Although the virus in feces is not enveloped, the density in serum was 1.15 to 1.16 g/mL in sucrose owing to an uncharacterized association with lipids.¹⁵¹ The sedimentation coefficient of HEV is 183S. Survival of HEV in the intestinal tract suggests that the virus is relatively stable to acid and mild alkaline conditions. HEV is more heat labile than is HAV.³⁸ Although not specifically tested, HEV is likely to be inactivated by the same agents that inactivate HAV, and chlorination is suggested to inactivate HEV in water.²³ HEV contains an RNA genome enclosed within a capsid that is probably composed of a single viral protein; however, insufficient virus has been available for purification and direct chemical analysis.¹⁵²

GENOME STRUCTURE AND ORGANIZATION

The genome of HEV mammalian genotypes 1 through 4 is a single-stranded, positive sense, polyadenylated RNA molecule of approximately 7.2 kb in length, excluding the poly(A)¹⁵² (Fig. 70.4). All three coding frames are utilized. A subgenomic, bicistronic messenger RNA (mRNA) is synthesized following infection.^{52,63} The genome consists of a $5'$ noncoding region of approximately 26 nucleotides that is capped with m⁷G at its $5'$ end,^{63,68,99} followed by ORF1 of approximately 5,100 nucleotides. Deletions or insertions within a hypervariable region (HVR) of ORF1 account for most size differences. ORF2

FIGURE 70.3. Proposed assembly scheme for hepatitis E virus (HEV) particles. Identical monomers and dimers are shown at the top: colors are added to aid visualization. Truncated HEV capsid protein (aa 112–608) forms A-B dimers that assemble into intermediate decamers and ultimately form small, empty, virus-like particles with $T = 1$ icosahedral symmetry. A slightly larger truncated HEV capsid protein (aa 14–608) similarly forms dimers and decamers that then interact with slightly differently oriented dimers (C–C) to form larger virus-like particles with a $T = 3$ icosahedral lattice. These larger particles can encapsidate RNA. (Courtesy of L. Xing and H. Cheng.)

begins in coding frame 2, which is 38 nucleotides $3'$ of the termination codon of ORF1, and consists of 1,977 to 1,980 nucleotides. A 65- to 74-nucleotide $3'$ noncoding region is contiguous with the termination of ORF2 and is terminated by a $3'$ stretch of 150 to 200 or more adenosine residues. ORF3, which is 348 to 351 nucleotides in length, extends 325 to 328 nucleotides into ORF2 in coding frame 3.

Avian HEV genomes have a similar organization but are 6.6 kb in length,^{57,111} whereas rat HEV has a genome that is 6.9 kb in length and has a similar arrangement of ORFs 1 through 3 plus three more possible ORFs.⁶⁵

Several ORF1 recombinant polypeptides have enzymatic activities. Methyltransferase and guanylyltransferase activities (MT) responsible for capping the viral genome are encoded within the $5'$ half of ORF1.⁹⁹ The RNA-dependent RNA polymerase (RdRp) responsible for replicating the genome and producing a subgenomic mRNA^{52,63} is encoded within the $3'$ half of ORF1.⁶ The upstream helicase domain exhibits RNA $5'$ triphosphatase, nucleoside triphosphatase (NTPase), and RNA unwinding activity and belongs to helicase superfamily 1.^{75,76}

FIGURE 70.4. Organization of the hepatitis E virus genome. The approximately 7.2-kb genome serves as messenger RNA (mRNA) and encodes three open reading frames (ORFs). The nonstructural proteins required for viral RNA synthesis are encoded within the approximately 5,100-kb ORF1 (see text for details). A bicistronic subgenomic mRNA of 2.2 kb encodes the ORF2 capsid protein, and the overlapping ORF3 encodes a small immunogenic protein proposed to have multiple functions. The *diamond* indicates a putative phosphorylation site on ORF3 protein, and the *asterisks* indicate three putative glycosylation sites on the ORF2 protein. The sequence of the genomic mRNA spanning the ORF1 translation stop codon and the methionine initiation codons for ORFs 2 and 3 are shown. The subgenomic mRNA starts at nucleotide 5,122 and thus does not include the two upstream methionine codons (AUG) in ORF3, which begins at nucleotide 5,104. A boxed 12-nucleotide-long *cis*-reacting element (CRE) controls subgenomic mRNA synthesis. MT, methyltransferase/guanylyl transferase; Hel, helicase; RdRp, RNA-dependent RNA polymerase; Y, Pro, H, and X domains, function not demonstrated. (From Graff J, Torian U, Nguyen H, et al. A bicistronic subgenomic mRNA encodes both the ORF2 and ORF3 proteins of hepatitis E virus. *J Virol* 2006;80(12):5919–5926.)

Conserved motifs found in proteins of other viruses suggest that ORF1 also encodes the following⁸⁵:

1. A Y domain, a sequence of unknown function found in certain other viruses, including rubella virus
2. A papain-like cysteine protease found predominantly in alphaviruses and rubella virus
3. A proline-rich hinge region that is thought to impart flexibility and that contains a region of hypervariable sequence
4. An X or “macro” domain of unknown function that flanks papain-like protease domains in the polyproteins of other positive-strand RNA viruses.⁷

However, none of the latter activities has been demonstrated to date.

ORF2 and ORF3 proteins are encoded by the same bicistronic subgenomic RNA^{52,63} (see Fig. 70.4). ORF2 capsid protein contains a typical signal sequence near its 5' end, immediately followed by a region rich in arginine and highly basic in charge, that may be involved in the encapsidation of the genomic transcript.^{147,152} The ORF2-encoded protein contains potential

glycosylation sites that are glycosylated *in vitro*; however, it has not been established that these are functional *in vivo*.^{157,174}

Because the subgenomic RNA that encodes ORF3 protein (see the Stages of Replication section) has a truncated reading frame 3, ORF3 protein contains 114 to 115 aa rather than the 123 to 124 predicted by the genomic RNA sequence.^{52,61,63} ORF3 protein is bound to virus particles in serum,¹⁵¹ as well as those produced in cell culture,^{40,151} and is required for virus release from cultured cells^{40,117,172} and for infection *in vivo*.^{51,61} However, ORF3 protein is not required for genome replication, viral assembly, or infection of hepatoma cells³⁹ *in vitro* and is not found on virus in feces.^{40,151} When overexpressed *in vitro*, ORF3 fractionates with the cellular cytoskeleton¹⁷⁵ and is phosphorylated, although phosphorylation is not required for viability *in vivo*.⁵¹ *In vitro*, overexpressed ORF3 does many things, suggesting that it may have regulatory functions (reviewed in reference 7). It interacts with nonglycosylated ORF2,¹⁶⁰ expedites the export of α 1-microglobulin and its precursor from hepatocytes¹⁶¹ and binds to Src homology 3 domains, and activates mitogen-activated protein kinase.⁸⁶ In addition, the HEV

genome contains at least two *cis*-reactive elements (CREs). One CRE overlaps the 3' end of ORF2 and the 3' noncoding region and is essential for replication⁴²; the second CRE may be the promoter for synthesis of the 2.2-kb subgenomic mRNA.^{22,51,52}

STAGES OF REPLICATION

HEV proves to be exceedingly difficult to culture. Tanaka et al.¹⁵⁴ reported the first propagation of a genotype 3 strain, isolated from a patient during the acute phase, and later reported the propagation of a genotype 4 strain, from a patient with fulminant hepatitis E.¹⁵⁵ In both cases, virus in feces was serially passaged in two human cell lines, A549 lung carcinoma and PLC/PRF/5 hepatoma. Another genotype 3 strain, isolated from a chronically infected patient, was propagated in the human HepG2/C3A hepatoma cell line; this cultured virus differed from the other two in that it infected swine cells as well as human cells and contained a large portion (174 nucleotides) of a human gene sequence inserted into the HVR.¹⁴⁵ The effect of this insertion on host range or disease manifestation is unknown; however, similar recombinants have since been isolated. The critical factor for achieving growth in cell culture was the titer of the virus inoculum^{124,149,150}; most likely, greater quasispecies diversity provides a variant with a constellation of mutations that permits propagation in cultured cells.

Much of the molecular biology of HEV is still unknown, and many steps are inferred from studies of other viruses (Fig. 70.5). A high-affinity cell receptor has not been identified; however, heparan sulfate proteoglycans may serve as a low-affinity receptor to promote initial contact.⁶⁹ The virus enters cells by an unknown mechanism. Heat shock protein 90 is implicated in the intracellular transport of the virus capsid early in infection.¹⁷⁸ The virus replication cycle is confined to the cytoplasm, and once the viral RNA is released from the capsid, ORF1 is immediately translated via cellular mechanisms that recognize capped mRNA.^{42,68,99} Transfected, capped genomes of HEV are able to replicate *in vitro*^{51,58,60,171} and cause infection *in vivo*.^{42,57,60} It is unclear if, or how, ORF1 protein is cleaved into subunits.

The newly translated RNA polymerase, guanylyltransferase, methyltransferase, and helicase/RNA triphosphatase activities of ORF1 protein would all be involved in RNA synthesis; it is not known if other regions of ORF1 protein participate. RNA synthesis probably occurs on the intracellular membranes.¹³⁸ The polyadenosine tract and stem-loop structures at the 3' end of the virion RNA mediate binding of recombinant polymerase to template RNA.⁶

The negative-strand replicative-intermediate would be synthesized first and serve as a template for capped genomic-sized mRNA and a capped bicistronic subgenomic mRNA that encodes ORF2 and ORF3 proteins.^{52,63} Twelve conserved nucleotides and a double stem-loop structure control subgenomic RNA synthesis.^{22,52} There is a temporal separation, and alternating cycles of negative- and positive sense RNA synthesis with the highest level of negative sense RNA (1,000-fold lower than positive sense) present at approximately 8 hours posttransfection; negative sense subgenomic RNA has not been detected.¹⁶³

ORF2 and ORF3 proteins are translated from two very closely spaced AUG codons on the same subgenomic mRNA; it is not clear how the relative translation of the two proteins is regulated.^{52,145} ORF2 capsid protein probably self-assembles into

virus particles in a reaction requiring viral RNA¹⁶⁹ (see the Morphology section). ORF2 protein in infectious virions has not been biochemically characterized; thus, although ORF2 protein contains a signal-like sequence at its 5' end and three internal sites that are glycosylated *in vitro*, it is not known if they function as such *in vivo*. The site of virus assembly is unknown.

Virions in serum^{124,150} or released into the medium of cultured cells are associated with lipids (uncharacterized) and ORF3 protein; they have a lower buoyant density than virions in feces and can be immune precipitated with anti-ORF3 if treated with nonionic detergent to disperse the lipids.^{40,172} Surprisingly, most virions in culture medium are not immune precipitated with antibodies to ORF2, unlike fecal virions. Therefore, virions produced in cell culture contain ORF2 protein that is masked or requires a maturation step. There are discrepant reports on whether ORF2 protein is more accessible to antibody when ORF3 protein is eliminated by mutagenesis, and on lipid association with intracellular virions and virions in feces^{40,172}. It has been suggested that detergents and proteases in bile and the intestine might remove these components.¹²⁴

ORF3 protein is not required for the production of infectious virions; however, it is important for virus exit from cells. ORF3 protein deletion mutants exit cultured cells inefficiently.^{40,172} Exit from the cells depends on an intact PXXP motif in ORF3 protein, which is conserved among all mammalian strains.^{40,117} Mutants with an altered PXXP motif are indistinguishable from ORF3 null mutants.^{40,117} The PXXP motif is believed to mediate binding to a host protein, perhaps Tsg101 in the vacuolar protein sorting pathway.^{7,172} Neither ORF3 null nor PXXP mutants are able to infect rhesus macaques.^{40,51}

PATHOGENESIS AND PATHOLOGY

The pathogenesis of hepatitis E is poorly understood. Some speculative conclusions can be drawn, however, from an analysis of the clinical and serologic events of a typical HEV infection (Fig. 70.6). Entry of the virus into the host is believed to be primarily by the oral route. The incubation period ranges from 2 weeks to 2 months. The site of primary replication has not been identified, although it is presumed to be in the intestinal tract. It is not clear how the virus reaches the liver, but it is presumably via the portal vein. It replicates in the cytoplasm of hepatocytes⁸⁷ and is released into the bile and blood by mechanisms that are not understood. Based on limited studies of oral infection in volunteers, viremia and fecal shedding are first detected about 3 weeks after exposure and about a week before onset of disease.^{16,27} Liver enzyme values peak about 7 to 8 weeks post exposure. Viremia may diminish at that time; however, fecal shedding may continue for days to weeks.

As in hepatitis A, specific immunoglobulin M (IgM) and immunoglobulin G (IgG) immune responses occur early in the disease, usually about the time of onset of clinical illness and peak of liver enzymes (see Fig. 70.6). IgM anti-HEV disappears after several months; IgG anti-HEV persists but at relatively rapidly decreasing levels shortly after infection.²¹ Anti-HEV can be detected for years after infection.⁸² It is not known whether such antibody eventually disappears or remains at low but detectable levels. Anti-HEV of the immunoglobulin A (IgA) class has also been detected in the serum of naturally infected individuals.²⁶ The significance of such antibody is unknown.

FIGURE 70.5. Hepatitis E virus (HEV) replication cycle. The diagram presents the most likely scenario for HEV replication based on current knowledge from studies of HEV and other plus-strand RNA viruses. **1:** Ingested virus is transported to the liver, where it binds nonspecifically to heparan surface proteoglycans. **2, 3:** The virus binds to a specific unidentified receptor (**2**) and is delivered to the cytoplasm where the plus strand genomic RNA is released from the capsid (**3**). **4:** Open reading frame (ORF) 1 is immediately translated to generate the nonstructural proteins required for viral RNA synthesis. **5, 6:** The newly synthesized polymerase proteins make a minus-strand copy of the genomic RNA (**5**), which serves as the template for amplification of the plus-strand genomic messenger RNA (mRNA) and for production of a bicistronic subgenomic mRNA by the polymerase proteins (**6**); both the genomic and subgenomic RNAs are capped; however, the 5' status of the minus strand is unknown. **7:** Both ORF2 and ORF3 proteins are translated from the same subgenomic mRNA. **8, 9:** ORF2 protein encapsidates the genomic mRNA (**8**), and ORF3 protein and lipids associate with the capsid (**9**). **10:** The virus is transported out of the cell and enters either the bloodstream or the bile duct; ORF3 and lipids remain on virus in the blood but are removed from virions by the time they are excreted in feces.

Virus found in the feces of infected humans or animals is presumed to be the primary source of infectious virus in the environment. Because large quantities of HEV have been found in the bile of experimentally infected primates, it is assumed that most virus in the intestinal tract originates in the liver.¹³⁹ In this respect, hepatitis E is similar to hepatitis A.

The severity of HEV infections is, on average, somewhat greater than the severity of HAV infections. Mortality of hepatitis E has varied in different reports but has been as high as 1%, compared to 0.2% for hepatitis A.¹³⁵ More important, however, is the severity of hepatitis E in pregnant women.^{1,23,64,78,84,137} The mortality of hepatitis E in pregnancy increases with each

FIGURE 70.6. Diagrammatic illustration of the clinical and serologic events in a typical case of acute hepatitis E. Antibody pattern depicted as measured by enzyme-linked immunosorbent assay (ELISA). Viremia and fecal shedding patterns are based on polymerase chain reaction (PCR) data. ALT, alanine aminotransferase. (Modified from Purcell RH, Hoofnagle JH, Ticehurst J, et al. Hepatitis viruses. In: Schmidt NJ, Emmons RW, eds. *Diagnostic Procedures for Viral, Rickettsial and Chlamydial Infections*. 6th ed. Washington, DC: American Public Health Association; 1989:957–1065.)

succeeding trimester and may reach 20%. In contrast, none of the other four recognized hepatitis viruses causes such severe hepatitis in pregnancy.¹¹⁵ The reason for the excessive mortality of hepatitis E in pregnancy is unknown, although a high viral load and abnormalities of progesterone signaling pathways have been suggested.^{20,64,74} HEV is an uncommon cause of fulminant hepatitis in nonpregnant individuals.^{90,123} Individuals with chronic liver disease of other etiologies are also at higher risk of severe, life-threatening hepatitis E.^{77,88,176} The hepatitis E mortality in such patients may be as high as 30%.

Although most HEV infections are self-limiting and resolve without sequelae, a significant proportion (>50%) of infected organ transplant patients or those with other types of immunosuppression may develop chronic infection that can progress to chronic hepatitis and cirrhosis.^{33,72,73,130}

Histologic changes in the liver of patients with hepatitis E include focal necrosis with minimal infiltration and no localization to a particular zone of the lobule. Modest inflammation consisting predominantly of Kupffer cells and polymorphonuclear leukocytes is seen, and the focal lesions resemble drug-associated toxic hepatitis. Cholestatic hepatitis is often present, characterized by ballooning hepatocytes, cytoplasmic cholestasis, and focal cytolytic necrosis. An unusual *pseudoglandular* alteration of the hepatocyte plates has also been recognized in some epidemics and sporadic cases (Fig. 70.7). The discrepancy between the time of appearance of viral replication in the liver and histopathologic and biochemical evidence of hepatitis suggests that HEV is not cytopathic and that the pathogenesis of hepatitis E is immunologically mediated. Alterations of both innate and adaptive immunity during acute infection have been reported; however, the mechanisms of pathogenesis are poorly understood.^{118,143,146,173}

Acinar transformation (“pseudoglandular” alterations) is indicated by arrows, and intraluminal cholestasis is depicted. Hepatocytes demonstrate “ballooning” and degeneration. (Courtesy of M. Sjogren.) (Reprinted from Purcell RH, Emerson SU. Hepatitis E. In: Mandel GL, Bennett JE, Dolin R, eds. *Principles and Practice of Infectious Diseases*. 6th ed. Philadelphia: Elsevier; 2005:2204–2217.)

EPIDEMIOLOGY

Hepatitis with clinical and epidemiologic characteristics of hepatitis E (peak clinical attack rate in young adults, high rate of

FIGURE 70.8. The age-related clinical attack rate of hepatitis E differs by genotype. Endemic disease associated with hepatitis (HEV) infections of genotype 1 or 2 in developing countries peak in the 20- to 29-year age group. This is similar to attack rates from HEV epidemics in the area. In contrast, clinical hepatitis E associated with infections of HEV genotype 3 or 4, often in industrialized countries, peaks in those 60 years of age or older. (Reprinted from Purcell RH, Emerson SU. Hepatitis E: an emerging awareness of an old disease. *J Hepatol* 2008;48:494–503.)

fulminant disease in pregnancy, epidemics of water-borne disease) has been reported in Southeast and Central Asia, the Middle East, Africa, and North America (Mexico).⁴ In 2004, a large outbreak among internally displaced persons in Darfur, Sudan, resulted in an unusually high case-fatality ratio of 18% among hospitalized patients, with pregnant women accounting for almost half of the deaths.^{19a} Epidemics in most of these regions have been confirmed serologically as hepatitis E, as has sporadic hepatitis occurring in many of the same regions.¹³¹ In fact, HEV is believed to be one of the most common causes of sporadic hepatitis in regions where the virus is endemic.

The age-specific clinical attack rate in developing countries, with its peak among young adults, is striking^{79,164,167} (Fig. 70.8). Clinical disease, however, has been found with similar frequency in all age groups in some epidemics¹¹⁶; clinical hepatitis E in children has also been reported.^{9,37,50,116} A male preponderance has been observed in some, but not all, epidemics. With the exception of a few food-borne epidemics, most serologically confirmed epidemics of hepatitis E have been associated with fecally contaminated water. In the 2004 Darfur outbreak, chlorinated water was implicated as one source of HEV.^{52a} Cases of probable sporadic hepatitis E have been linked epidemiologically to consumption of raw or uncooked shellfish²⁴ or, more commonly, of undercooked pork, offal, or wild game.^{32,105,107,108,126,127,133,148,153} The epidemiologic risk factors associated with most sporadic cases of hepatitis E have been difficult to identify. Person-to-person

spread from cases to contacts has been reported; however, this appears to be relatively uncommon and, in fact, has been questioned.^{3,23,37,80,120,156} Evidence for a higher risk of infection with HEV among healthcare professionals is not convincing,¹²² although transmission via exposure to blood has been documented in regions where the virus is endemic and, rarely, in industrialized countries.^{2,15,48,83,104,168} Infants of mothers with hepatitis E are also at risk of being infected perinatally.⁸⁹ HEV RNA has been detected in colostrum from infected mothers; however, there is no epidemiologic evidence that suggests transmission to offspring by nursing.²⁸ Travel to an area where HEV is endemic has been a risk factor in several cases,^{25,46} and one hospital-related outbreak has been reported.¹⁴⁰

The recent development of sensitive serologic tests for infection with HEV has permitted a more complete analysis of the worldwide distribution and seroprevalence of HEV infection. Surprisingly, with a few exceptions,⁴⁵ the prevalence of IgG antibody to HEV in suspected or documented endemic regions has been much lower than expected, and the prevalence of such antibody in nonendemic regions has been much higher than anticipated¹³¹ (Fig. 70.9). For instance, anti-HEV seroprevalence in the U.S. population was estimated to be 21% even though hepatitis E was rarely reported.^{89a} Except in epidemic settings¹¹⁶ and limited other instances,^{5,45} the prevalence of anti-HEV in infants and children has also been low.^{14,92,97,116} The greatest increase in prevalence of anti-HEV has occurred in young adults—the age group at highest risk of clinical

FIGURE 70.9. Age-specific prevalence of anti-hepatitis E virus (HEV) in different regions. The prevalence of anti-HEV in India and the peak age of antibody acquisition (16–25 years) is lower and later, respectively, than expected for a fecally transmitted virus. In contrast, the prevalence of anti-HEV in the United States is higher than expected, given the rare diagnosis of hepatitis E. Finally, the prevalence of anti-HEV in Egypt is particularly surprising because, in contrast to India, water-borne epidemics of hepatitis E are virtually never reported. All of the anti-HEV enzyme-linked immunosorbent assay (ELISA) tests were performed with the same assay. (Reprinted from Purcell RH, Emerson SU. Hepatitis E: an emerging awareness of an old disease. *J Hepatol* 2008;48:494–503.)

disease in developing countries^{14,92,97} (see Fig. 70.9). Some years ago, virtually identical age-specific anti-HEV and anti-HAV patterns were detected in the same population in India over a decade, suggesting that endemic exposure was continuing.¹⁴ Since then, there is evidence that both viral infections are diminishing in the population, especially among those of higher socioeconomic status, and similar changes appear to be occurring in other developing countries. In industrialized countries, there is invariably a higher prevalence of antibody among older individuals, suggesting a cohort effect signaling diminished exposure to the virus in more recent times. Indeed, such a cohort effect was recently demonstrated in Denmark²⁹ (Fig. 70.10). Thus, in some settings, the epidemiologic characteristics of HEV appear to differ significantly from those of viruses such as HAV, which are readily transmitted by the fecal–oral route. These may be reflections of the differences in amount and duration of viral shedding, relative stability of the viruses to environmental factors, and the differential role of zoonotic exposure.

The impact of HEV infections in various wild and domesticated animals on the epidemiology of hepatitis E in humans is the subject of much debate (see Table 70.1). The close genetic relationship between swine HEV strains and strains of HEV isolated from humans living in the same geographic regions suggests that transmission from swine to humans can occur (Figs. 70.11 and 70.12). This hypothesis is strengthened by the demonstration of HEV (transmissible in one instance) in commercial pig livers in several countries, the recovery of virtually identical HEV sequences from hepatitis E cases and food they had eaten, and a higher prevalence of anti-HEV in those who have had greater contact with swine and swine products.^{108,127,133}

FIGURE 70.10. Prevalence of anti-hepatitis E virus (HEV) in Danish blood donors, farmers, and prisoners who were bled at different times (1983–2003). The data are plotted by year of birth and are interpreted to demonstrate the Cohort Effect, in which individuals born early in the 20th century were more likely to be exposed to HEV than those born later in the century. Similar patterns of antibody to hepatitis A virus were also found, suggesting that both viruses were more common at an earlier time. (From Christensen PB, Engle RE, Hjort C, et al. Time trend of the prevalence of hepatitis E antibodies among farmers and blood donors: a potential zoonosis in Denmark. *Clin Infect Dis* 2008;47(8):1026–1031.)

Indeed, cases of hepatitis E in industrialized countries that are associated with infection by swine-like strains occur in older individuals or those with impaired immunity (see Fig. 70.8), and such infections with strains that can replicate in swine (genotypes 3 and 4) tend to be less severe than those caused by exclusively human strains (genotypes 1 and 2). Thus, in developing countries where human and swine strains coexist, the more virulent human strains predominate clinically. However, in industrialized countries where human strains cannot sustain themselves in the environment, swine strains are the predominant strains associated with disease (Fig. 70.13). However, zoonotic transmission of HEV from swine to humans cannot explain endemic cases of hepatitis E that occur in regions where swine are uncommon and not eaten for religious or other reasons. The recent recovery of genotype 4 HEV from cattle and sheep in China suggests that these important components of the human food chain (along with goats) might be important vectors of transmission, although this has yet to be demonstrated.^{56,165} Neither avian HEV nor rat HEV is thought to be transmissible to humans, because neither is transmissible to rhesus monkeys—a sensitive host for the four principal mammalian HEV genotypes and a surrogate of man.^{113,134}

Molecular approaches to the epidemiology of HEV hold some promise. Reverse transcription polymerase chain reaction (RT-PCR) has been useful for confirming the results of serologic tests and for estimating the duration of infectivity of individual cases.²⁷ It is less sensitive, however, than serologic tests for diagnosis of acute hepatitis E and of limited value for molecular-epidemiologic studies because of the relatively short

FIGURE 70.11. Each of the four genotypes of hepatitis E virus that infect humans has a distinct—and in some cases, overlapping—geographic distribution. Uncolored areas lack sufficient information. (Reprinted from Purcell RH, Emerson SU. Hepatitis E: an emerging awareness of an old disease. *J Hepatol* 2008;48:494–503.)

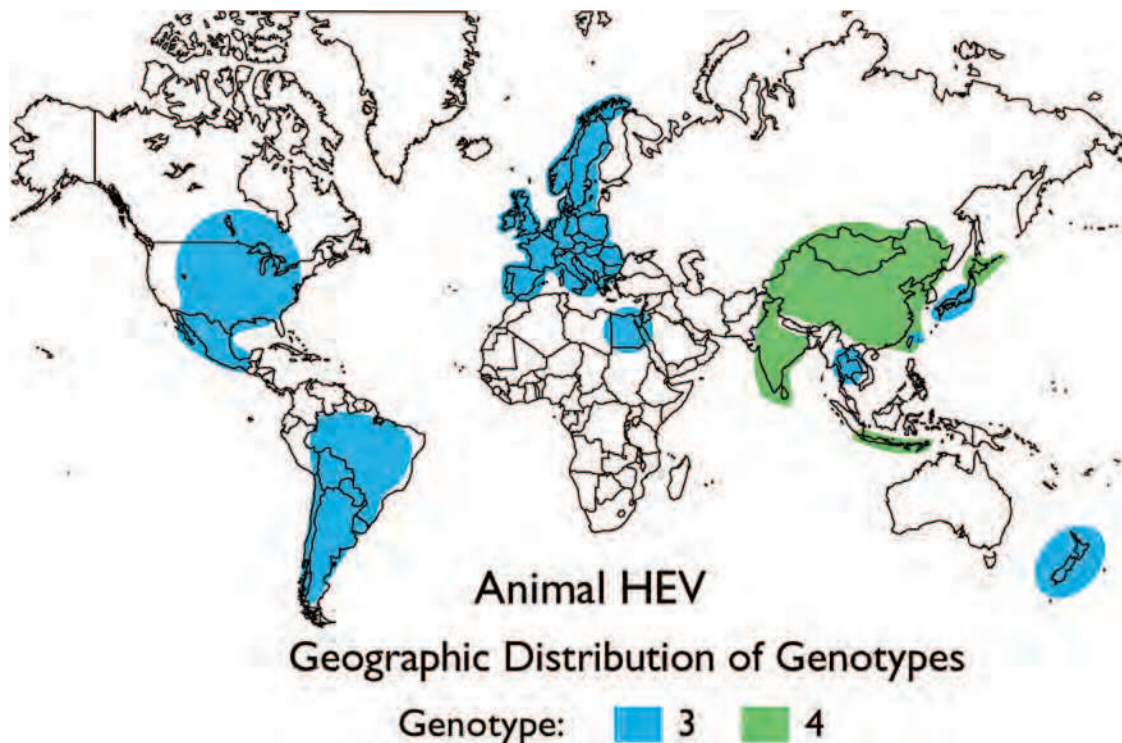

FIGURE 70.12. Hepatitis E virus genotypes 3 and 4, which infect both humans and swine, have been recovered from pigs (and occasionally other animals) in regions that roughly parallel distribution of these viruses in human infections. However, there are exceptions (see Figure 70.13). (Reprinted from Purcell RH, Emerson SU. Hepatitis E: an emerging awareness of an old disease. *J Hepatol* 2008;48:494–503.)

HEV Infections: Developing vs Industrialized Countries

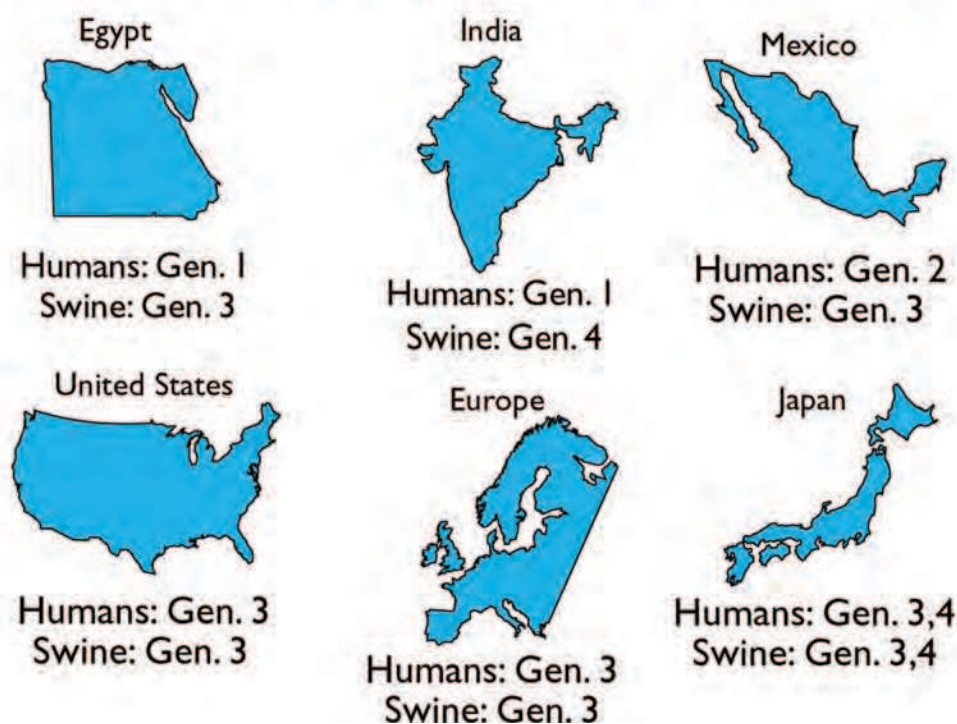

FIGURE 70.13. In many countries where human hepatitis E virus (HEV) genotypes 1 or 2 are endemic, these viruses are responsible for the most human clinical infections, even though swine HEV genotypes 3 or 4 are endemic in local swine herds. In regions where the human HEV genotypes cannot persist, presumably for reasons of sanitation, swine HEV strains occasionally cause human disease, probably by ingestion or other contact with infected pigs.

duration of viremia and fecal shedding. Its main value in this regard has been the identification of HEV genotypes and their relationship to specific epidemics and geographic locations. In addition, RT-PCR has been used to detect HEV in contaminated water and sewage.^{30,91,129,162}

CLINICAL FEATURES AND COURSE

Individual cases of hepatitis E cannot be differentiated from other cases of hepatitis on the basis of clinical presentation.¹³⁷ In fact, clinical features are of limited usefulness in the diagnosis of acute hepatitis caused by any of the recognized viruses.¹³⁵ Sensitive serologic tests have revealed that not all HEV infections are clinically apparent.²¹ In epidemics, however, most patients will experience jaundice, anorexia, and hepatomegaly. Approximately half of the patients will experience abdominal pain and tenderness, nausea and vomiting, and fever. Sequelae and extrahepatic manifestations of infection include various neurologic manifestations, including inflammatory polyradiculopathy, Guillain-Barré syndrome, encephalitis, and various neuropathies and myopathies.^{47,71,98,101} These have been diagnosed in patients with acute, self-limiting hepatitis E as well as in immunosuppressed patients with chronic infection. HEV has also been detected in the cerebrospinal fluid of some of these patients.⁷¹ Most reports of neurologic sequelae have been in European patients infected with genotype 3, presumably via

zoonotic exposure. In Asian pregnant patients with severe hepatitis E, excess fetal wastage and premature deliveries with a high infant mortality rate have been reported.

DIAGNOSIS

Hepatitis E should be suspected in outbreaks of water-borne hepatitis occurring among citizens of developing countries, especially if the disease is more severe in pregnant women. In the United States and Europe, hepatitis E should be suspected in a patient with hepatitis who has recently returned from an endemic region. In addition, hepatitis E has been reported with increasing frequency in individuals who have not traveled to an endemic region. These cases, principally from Europe but also from other regions, including the United States and Japan, may be associated with eating undercooked pork or wild game or other contact with potentially infected animals. As with all types of viral hepatitis, serologic tests are necessary to establish a definite diagnosis. Specific tests for IgM and IgG antibodies to HEV have been developed and are commercially available in Europe, Asia, and elsewhere, but not in the United States, where the diagnosis of hepatitis E remains an experimental procedure. Current tests are capable of detecting IgM anti-HEV in up to 90% of acute infections if a serum sample is obtained 1 to 4 weeks after the onset of disease.^{21,43,50,116} IgM anti-HEV reaches peak titers during the first 4 weeks after the onset of hepatitis,^{10,21} and by

FIGURE 70.14. Variation in sensitivity of commercial tests for detecting immunoglobulin G anti-hepatitis E virus (HEV) when tested against World Health Organization Anti-HEV Standard 95/584. The titer of the standard differed by 24-fold when tested with the most and least sensitive tests. These tests are licensed and available in several countries; however, no test is licensed and commercially available in the United States. Consequently, it is thought that at least some cases of hepatitis E remain undiagnosed.

3 months after the onset of disease, IgM is no longer detectable in 50% or more of patients with hepatitis E.^{10,16}

A rising titer of IgG anti-HEV is also diagnostic. IgG anti-HEV peaks in titer between 2 and 4 weeks after onset of hepatitis and diminishes relatively rapidly thereafter.^{10,21,35} It is not clear how long IgG anti-HEV persists at detectable levels. Serologic tests continue to vary greatly in sensitivity and specificity^{19,36,103} (Fig. 70.14).

Molecular approaches (nested RT-PCR, real-time polymerase chain reaction [PCR]) are useful for detecting HEV in blood and feces during the acute phase of infection. They have contributed to the identification of new genetic variants of HEV^{114,141}; however, the sensitivity of the technique depends on a proper match between the HEV strain and the PCR primers.^{18,141} More broadly reactive RT-PCR primers that can detect most, if not all, mammalian HEV strains have recently been described.⁶⁶ Thus, serologic and molecular approaches to diagnosis are complementary.⁵⁹

TREATMENT

No specific treatment exists for acute hepatitis E. Both interferon alpha and ribavirin have been used successfully to treat chronic HEV infections.^{54,70,73,100} Aggressive management of fulminant hepatitis E may reduce the mortality of this complication in pregnant women.⁶²

Access to a clean water supply and cooking meats to a temperature that inactivates HEV should, in theory, greatly decrease the incidence of HEV infections. HEV is only partially inactivated at 56°C.^{38,154}

Interdiction

Improved personal and public hygiene appears to have resulted in a reduction in the incidence of HEV infections in industrialized

countries and more recently in developing countries; however, paradoxically, more cases of hepatitis E are being reported now than previously, probably because of improving diagnostic tests, better surveillance, and a higher index of suspicion. Hepatitis occurring in Europe before the 20th century, which was believed at that time to have been hepatitis A, had the epidemiologic characteristics of hepatitis E.³¹ Thus, HEV—more labile and shed in lower titers than HAV—may have largely disappeared from more industrialized countries in the recent past, just as HAV is diminishing in importance in these countries; seroepidemiologic studies of HEV and HAV in Denmark are consistent with this interpretation.²⁹ Regions where HAV is still highly endemic may, however, also harbor endemic HEV.^{8,14,92} It is worth noting that this *labile* virus was still infectious when recovered from sewage in Spain, a country in which the virus is not highly endemic.¹²⁹ The high prevalence of anti-HEV in domestic and wild animals, even in industrialized countries, and the epidemiologic association between hepatitis E and ingestion of undercooked pork and wild game are evidence that zoonotic spread of HEV can continue in such regions, despite improved sanitation.^{13,34,93,109,112,121,166}

IMMUNOPROPHYLAXIS

Attempts to prevent or modify hepatitis E by the administration of normal immune globulin manufactured from source plasma obtained in the areas where HEV is endemic have been unsuccessful^{23,67,80} or uncertain.¹⁵⁸ Because most of these studies were performed before the development of sensitive and quantitative tests for anti-HEV, the lots of globulin employed were not tested for the presence or titer of anti-HEV. Because even populations in regions where HEV is endemic have a relatively low prevalence and titer of anti-HEV (see earlier discussion), it is perhaps not surprising that unselected lots of normal immune globulin may not contain protective quantities of anti-HEV. Limited experimental studies in primates suggest that passively acquired anti-HEV (convalescent or monoclonal) modifies but may not prevent HEV infection.^{142,159}

Vaccine

Neutralization epitopes for the capsid protein are conformational and encompass approximately 150 aa (aa 458–607) of this 660 aa protein.^{106,179} This region of the capsid protein also contains elements that are essential for homodimer formation and assembly into VLPs, both associated with eliciting neutralizing antibodies.^{94–96} Homodimers, the smallest units that can interact with neutralizing antibodies and stimulate protection, spontaneously form VLPs that share the antigenic characteristics of homodimers^{94,169,170} (see Fig. 70.3). Both the homodimer and VLP forms of the truncated capsid antigens, whether expressed from baculovirus or *Escherichia coli*, have been highly antigenic and suitable for use as vaccines. The four genotypes of HEV that infect humans constitute a single serotype, and challenge studies in monkeys demonstrated protection across genotypes.^{136,137} Vaccines for the prevention of hepatitis E are not commercially available. Candidate recombinant hepatitis E vaccines, expressed from the capsid gene of HEV in *E. coli* or from baculovirus in insect cells, however, have been shown to be highly protective in clinical trials^{144,180} (Table 70.2).

TABLE 70.2 Candidate Hepatitis E Vaccines

Vaccine manufacturer	Antigen (genotype 1)	Expressed from	Dose	HEV genotype in vaccinated population	Efficacy (95% CI)
GlaxoSmithKline (Belgium)	Recombinant capsid protein (aa 112–607)	Baculovirus in insect cells	20 µg with alum	1	95.5% (89–99)
Xiamen Innovax Biotech (China)	Recombinant capsid protein (aa 368–606)	<i>E coli</i>	30 µg with alum	4	100% (72–100)

T-cell responses in hepatitis E have not been extensively characterized. However, a recently developed interferon gamma Elispot assay that was sensitive and quantitative should prove useful because it correlated strongly with anti-HEV results from human subjects and detected specific cell-mediated immune responses to HEV in convalescent chimpanzees 3 to 4 years after experimental infection.¹⁴³

PERSPECTIVES

Considerable progress has been made in understanding HEV since the virus was first identified in 1983. Four genotypes have been characterized and more are being discovered, their worldwide distribution is being determined, and two recombinant vaccines have completed clinical trials and have been shown to be highly protective. HEV has been recovered from numerous species of animals, and the zoonotic transmission of HEV has been documented.

In contrast to these advances, the lack of a reliable cell culture system had inhibited studies of the molecular biology of this virus; however, this is changing, as new cell culture systems and new sources of virus (e.g., from chronic infections) have recently become available.

Future studies are expected to determine whether (or which) animal reservoirs are the most important sources of human infection. The hypothesis that circulating naturally avirulent strains are common in some countries needs to be examined, as does the possibility that frequent contact with low levels of virus protects against disease. We need to know why and how the virus causes uniquely high mortality in pregnant women. Also, a commercially available licensed test is desperately needed in the United States so that cases of idiopathic hepatitis might be diagnosed.

In summary, many questions concerning the biology, pathogenesis, epidemiology, and immunology of HEV remain unanswered, and the tools to answer these questions are just now becoming available.

ACKNOWLEDGEMENT

This work was supported by the Intramural Research Program of the National Institute of Allergy and Infectious Diseases.

Giant Viruses Associated with Protists Challenge the Definition of Viruses and Lead to Proposal of the Fourth Domain Theory

Conclusion

The serendipitous discovery in 2003 of *Acanthamoeba polyphaga mimivirus* led to groundbreaking findings and, subsequently, fed several debates regarding the evolution, origin, and definition of viruses.^{42,76,113,114} Although several uncommonly large viruses had already been discovered since the 1960s, the Mimivirus capsid was larger than those known earlier, and the Mimivirus gene content was broader than that of any other known virus. In addition, several genes encoding proteins involved in amino acid, carbohydrate, or lipid metabolism, among which some had never been previously found in viruses, are present in the Mimivirus genome. Taken together, Mimivirus changed our vision of the viral world. The size and gene repertoire of Mimivirus deeply challenged the canonical definition of viruses, which had historically been considered as small “ultra-filterable” entities. Indeed, viruses were mostly defined on the basis of negative criteria, including the fact that

they were not retained by a porcelain filter and were not visible using light microscopy, in contrast with bacteria.^{6,57,84,115} Moreover, viruses were removed from the tree of life, which contains bacteria, archaea, and eukaryotes,^{96,142} based on the absence of genes shared with members of these three recognized domains of life. Furthermore, the increased knowledge of giant viruses reactivated the debate about whether or not viruses are alive.^{41,96,114}

Following Mimivirus, other giant viruses have been recovered from *Acanthamoeba* spp., including Mamavirus, a new strain of Mimivirus, and Marseillevirus and Lausannevirus, which are close relatives.^{15,28,78,133} In addition, another giant virus has been described in *Cafeteria roenbergensis*, a marine dinoflagellate protist, but was nonetheless classified within the family *Mimiviridae*.³⁹ Moreover, based on new high-throughput protocols for amoebal culture, La Scola et al⁷⁷ identified 19 new giant viruses infecting *Acanthamoeba* spp., among which several can be classified within the family *Mimiviridae*. Furthermore, viruses infecting Mimivirus, Mamavirus, and *Cafeteria roenbergensis* virus were also discovered, which led to the concept of “virophages” based on functional similarity with bacteriophages.⁷⁸

MIMIVIRIDAE

Acanthamoeba Polyphaga Mimivirus

History and Discovery

Mimivirus was discovered in water collected from a cooling tower in Bradford (England) through the use of culture on amoebae.⁷⁶ Mimivirus was part of a collection of pathogens isolated by Dr. Tim Rowbotham by culturing on the amoeba *Acanthamoeba polyphaga* to investigate a pneumonia outbreak.¹¹⁵ Several bacteria that are pathogenic in amoebae were identified by this approach, but no other agent could be identified. Only the use of electron microscopy to understand the mechanism by which this agent resisted protocols that were used to amplify and detect its nucleic acid led to the discovery of Mimivirus. Notwithstanding, Mimivirus was visible by optical microscopy and appeared as a gram-positive coccus after staining.^{76,115} Therefore, it was surprising to find viral particles using electron microscopy of a size greater than that of two dozen bacteria, which led to consideration initially and for several months of these particles as bacteria, not viruses. Later, the genome of Mimivirus was sequenced and, congruently with the particle size, was revealed as the largest sequenced viral genome.¹¹³

Scale bars indicate 100 nm.

Structure

GENERAL SHAPE

The Mimivirus structure was studied through different approaches, that is, by means of traditional transmission electron microscopy (TEM) of thin sections, scanning electron microscopy (SEM), cryoelectron microscopy (cryo-EM), electron tomography, x-ray crystallography, atomic force microscopy (AFM), and x-ray laser.^{64,74,75,122,144,145,149} Taken together, these studies revealed a complex structure for a virus as well as structural relationships to other viruses including, for instance, phycodnaviruses (e.g., *Paramecium bursaria chlorella* virus 1 [PBCV-1])¹³⁵ and the infectious bursal disease virus.^{11,64} The Mimivirus virion size is ~750 nm, as demonstrated using EM (Fig. 71.1).^{75,76} Along with making Mimivirus the largest known virus thus far at time of its discovery, its huge size is of the same order of magnitude as intracellular bacteria, such as *Rickettsia conorii* and *Tropheryma whippie*, and it is even greater than that of very small bacteria, such as *Ureaplasma urealyticum*.^{76,130} EM and cryo-EM revealed that Mimivirus has an icosahedral shape with a vertex-to-vertex diameter of ~500 nm (Fig. 71.2).^{64,76,144} However, the shape of the virion does not display ideal icosahedral symmetry due to the presence of a starfish-shaped structure at one icosahedral fivefold vertex (Figs. 71.2 and 71.3).⁶⁴ The five faces supporting the

starfish are inclined by ~5% compared to what would correspond to an ideal icosahedral capsid.¹⁴⁵ Only one fivefold symmetry axis does exist, which passes through this special vertex.

OUTER FIBERS

Fibers ~120 to 140 nm in length and ~1.4 nm in diameter are present on almost all of the surface of the viral capsid (Fig. 71.1D, E; Fig. 71.2B). The fibers are closely packed and compose a dense layer.^{64,75} These fibers are extensively glycosylated, peptidoglycan likely protecting them from proteolysis.⁷⁵ This is suggested by AFM images, by resistance of fibers to proteases unless they have been previously treated with lysozyme, and by the initial observation that Mimivirus was gram positive after staining.^{76,115,145} These fibers are suspected to be helicoidal and polar.⁷⁵ They were also suspected to be composed of collagen,^{113,144} but this hypothesis has since been ruled out.⁷⁵ The fibers seem to be fabricated apart from the viral particle and to be attached to the viral particle at a late stage during the viral assembly pathway.^{129,149} Successive rings of density separated by 20 to 50 nm have been observed on the fibers after partial treatment with bromelain, which appear to be different segments.¹⁴⁵ At their distal ends, outer fibers are linked to a small globular shape that has an estimated size of 3.5×5 nm.^{75,145} Multiple surface fibers, possibly in groups of three or four, may

FIGURE 71.2. Schematic of the structure of Mimivirus particles. A: The whole viral particle. **B:** The outer fibers, the capsid, and the membrane of the sac that contains the DNA genome. (Adapted from 64.)

be attached at their proximal extremity to a disc-shaped anchor protein or to a capsomer.^{75,145} Indeed, an anchor layer seems to connect the fibers to the capsid lattice. It appears to be composed of proteins arranged in a closely packed array of likely common structures that protrude from the capsid surface by ~3 to 4 nm.⁷⁵ The anchor protein may be the capsomer itself, corresponding to large extended loops that would protrude

from the double jelly-roll structure of the major capsid protein (MCP).¹⁴⁴ Alternatively, the anchor structure may be composed of other proteins that lay upon the capsid shell.

CAPSID

The Mimivirus MCP has a double jelly-roll fold,⁶⁴ as in other large double-stranded DNA (dsDNA) viruses, including

FIGURE 71.3. Electron microscopy showing vertices of Mimivirus particles. Star-shaped structures (indicated by solid arrows) as visualized by transmission electron microscopy. The dashed arrow in **A** shows a star-shaped structure sliced in its center, forming a membrane conduit. Scale bars indicate 200 nm.

FIGURE 71.4. Schematic of capsomer arrangement in the Mimivirus capsid. A: Arrangement of capsomers with p6 symmetry in the Mimivirus capsids. **B:** Honeycomb array appearance composed by alternating hexagonal rings of capsomers and depressions. (Adapted from 145.)

PBCV-1, *Sulfolobus* turreted icosahedral virus, adenoviruses, and bacteriophages PRD1 and PM2.^{9,145} The L425 protein is the most abundant capsid protein in Mimivirus, and it shares substantial amino acid sequence similarity (31%) with the Vp54 protein of PBCV-1.¹⁴⁴ Capsomers are hexameric and are composed of three monomers of the MCP, each of which is formed by two consecutive jelly-roll folds (Fig. 71.4A).¹⁴⁵ In Mimivirus, an insertion in the DE loop of the second jelly-roll motif is particularly long (190 amino acids). These amino acids form a tall tower-like insertion, which is similar to that found in adenoviruses.¹⁴⁵ The Mimivirus capsid has a p6 plane organization and a 2T/3 estimated number of jelly-rolls; the distance between capsomers is 81 Å (Fig. 71.4A).¹⁴⁵ Depressions separated by 14 nm and organized in a hexagonal array are present on the viral surface, as determined by cryo-EM and AFM (Fig. 71.4B).¹⁴⁵ Six capsomers arranged with p6 symmetry surround each depression. This arrangement has the appearance of a honeycomb with alternating hexagonal rings and depressions. The triangulation number (T) of the Mimivirus capsid can only be estimated due to the insufficient resolution of the hexagonal lattice on the viral surface, and it is within the range of 972 to 1,200.⁶⁴ It was observed that each equilateral triangular face contains 19 rows of depressions, which are parallel to the edge and comprise one less depression from one row to another away from the edge.¹⁴⁵ Kuznetsov et al⁷⁵ pointed out that the Mimivirus MCPs may interact in a very flexible manner with their neighbors, or they may have a broad range of conformations, to provide such a continuous smooth aspect to the icosahedral surface. In fact, the capsid seems to have three layers of dense matter, consisting of a ~7-nm-thick protein shell that surrounds two successive 4-nm-thick lipid membranes separated by 6 nm (Fig. 71.2).¹⁴⁴

Thus, the inner capsid surface differs from the outer surface and is suspected to be coated with a lipid membrane associated with proteins or a layer of proteins.^{75,149} The length of the edges of the capsid is estimated to be ~250 nm. Thus, the interior volume may be $\sim 3.4 \times 10^7 \text{ nm}^3$ with only two-thirds of this space filled with the DNA genome, proteins associated with the genome, and the membrane sac.⁷⁵

INNER LAYERS AND NUCLEOCAPSID

The presence of an inner lipid membrane, which surrounds the central core, is shared with other nucleocytoplasmic large DNA viruses (NCLDVs), including phycodnaviruses and African swine fever virus.^{144,149} Beneath the capsid and the two electron-dense layers, at a distance of 300 to 500 Å from the outer capsid, is a lipid bilayer sac that surrounds the genome (Fig. 71.2).^{75,145} The nucleocapsid forms the central electron-dense core of the Mimivirus. It displays a large depression that faces the starfish-associated vertex and is separated from it by a low-density space constituting a cavity that is hypothesized to contain enzymes required for infection (Figs. 71.1 and 71.2).^{144,145} The nucleocapsid is held within the virus in such a manner that the depression constantly faces the special vertex and that the distance between the outer capsid and the sac surrounding the genome remains stable. It has been observed that ~1.2-nm-diameter internal fibers with a 7-nm periodicity are present in the space between the inner capsid surface and the sac containing the DNA, and they might support this architecture (Fig. 71.2).^{75,144} These fibers are long and flexible, and they may be extended arrangements of coiled-coil protein polymers, similar to those composing keratin, myosin, or kinesin.^{54,74} In contrast, however, they are unlikely to be constituted by successive protein subunits or to be polysaccharides or nucleic

acids.^{74,75} These fibers may be glycosylated, at least over some lengths, and were occasionally associated with toroidal complexes, which are presumed to be enzyme complexes that may modify the fibers by synthesizing and then attaching oligosaccharides.⁷⁴ Notably, these fibers appear capable of producing ribbons via a multiple-strand side arrangement as well as thick cables by twisting about one another.⁷⁴

The Mimivirus DNA chromosome exists in a sac whose diameter is estimated to be ~340 nm, corresponding to an approximate spherical volume of $2.1 \times 10^7 \text{ nm}^3$.⁷⁵ DNA shed by experimentally pressing viral particles appears as single strands with many turns and loops. Various proteins that are associated with the genome and that differ in both size and shape can be observed (Fig. 71.2). Based on the length of the DNA genome, its packing density is $\sim 0.06 \text{ nm}^3/\text{bp}$.^{75,113} This density is on the same order of magnitude as that estimated for the vaccinia virus⁷³ but is more than 10 times lower than for bacteriophages lambda and P22.⁷⁵ Nevertheless, Mimivirus and vaccinia virus DNA are associated with proteins, whereas the genomes of the two latter bacteriophages are not.

STARFISH-SHAPED STRUCTURE

Each Mimivirus harbors a starfish structure at one icosahedral fivefold vertex (Figs. 71.2, 71.3, and 71.5A). The arms of this starfish nearly extend to the five nearest surrounding vertices (Figs. 71.2 and 71.5).^{64,75} They are ~200 to 250 nm in length, ~50 nm in width, and ~40 nm in thickness.^{75,149} These arms are integrated into the capsid network, protruding above the capsid surface by ~20 nm, and they do not lie on capsid proteins but display a structural continuity with the capsid network on their edges.⁷⁵ The composition of these starfish arms remains unknown. They are thought to be constituted of proteins that are different from the MCP because they are devoid of hexagonal arrays of depressions.¹⁴⁵ Nevertheless, they suffer no damage when exposed to cysteine and serine proteases.⁷⁵ The starfish is not coated with fibers or with a layer of anchoring proteins, and it therefore forms a starfish-shaped depression on the surface of viral particles that harbor fibers.¹⁴⁹ The outer shell at this location has a partially open configuration that is sealed by the underlying inner shell (Fig. 71.5). The starfish-shaped structure may be a gate for the internal viral content to move to the amoebal cytoplasm.¹⁴⁹ Special vertices allowing viral genome exit have also been described in other large dsDNA viruses, including PRD1,⁵¹ as well as herpesviruses and tailed bacteriophages.^{3,62,145}

UNCOMMON MORPHOLOGICAL ASPECTS OF MIMIVIRUS

Various uncommon morphological aspects have been observed for Mimivirus particles, including some showing uncondensed core material.¹³⁰ Some of these observations are suggested to correspond to immature or defective particles. Moreover, La Scola et al⁷⁸ reported atypical morphological features for Mamavirus, another strain of Mimivirus, when infected with the Sputnik virophage (see the section on the Sputnik virophage) (Fig. 71.6).

Genomics

GENOME SIZE AND SHAPE

The Mimivirus genome was described in 2004.¹¹³ It is a ds, linear DNA molecule of ~1.18 megabase pairs, as attested by restriction digests and pulse-field gel electrophoresis (Fig. 71.7A).¹¹³ This genome became therefore the largest among viral genomes, being even larger than the genomes of several parasitic bacteria.⁶⁶ The Mimivirus chromosome is AT rich (72%). It has been hypothesized that the Mimivirus genome may adopt a circular conformation by means of pairing between inverted repeats ~600 nucleotides (nt) in length; due to location of these repeats toward the extremities of the genome, the circular chromosome would have two tails, a short one (~250 nt) and a longer one (~22,500 nt).^{20,113}

GENOME ORGANIZATION AND ANNOTATION

A total of 1,262 putative open reading frames (ORFs) were first identified in the Mimivirus genome, of which 911 have been predicted to encode proteins while the DNA also exhibited 6 tRNA (Fig. 71.7B).¹¹³ The DNA molecule has therefore a coding density of 90.5% and a mean intergenic space of 157 nt.¹¹³ Noteworthy, the Mimivirus genome harbors ~2.5 times as many genes as *Mycoplasma genitalium* or the archaeon *Nanoarchaeon equitans*.⁶⁶ The predicted genes are evenly distributed on both strands, with 450 and 461 ORFs located on negative and positive strands, respectively; they tend to be located far from a hypothetical origin of replication.¹¹³

A total of 298 ORFs have been annotated as having a functional attribute, which corresponded to approximately one-quarter of the predicted gene content. This proportion is low compared to that of the genomes of small bacteria and archaea, which is ~70%.⁴⁶ Among the Mimivirus ORFs, 194 could be assigned to 108 clusters of orthologous groups of proteins (COGs)¹¹³ corresponding to 17 functional categories (COGs are groups of three or more proteins present in

FIGURE 71.5. Schematic of the star-shaped structure and the opening of the five triangular faces of the capsid at the special vertex. The special star-shaped vertex is covered by the starfish structure arms (A), which detach from the viral particle (B) before the five triangular faces of the capsid underneath open outward (C).

distant genomes and more similar to each other than to any other proteins within the same genome) (Fig. 71.8).¹³¹ In 2010, the Mimivirus genome was resequenced using SOLiD ultra deep genome and transcriptome sequencing, then reannotated by Legendre et al.^{81,82} (GenBank accession no.: NC_014649.1). The new version of the genome has a length of 1,181,549 bp and was predicted to harbor 1,018 genes consisting of 979 genes that putatively encode proteins, 33 noncoding RNAs, and 6 transfer RNA (tRNA). Additionally, comparison of the Mamavirus and Mimivirus genomes enabled the amendment of the annotation for 159 ORFs (16%) of this new version of the Mimivirus gene content, which includes helicases and primases, kinases, endo-/exonucleases, methyltransferase, and adenosine triphosphatase (ATPase)/guanosine triphosphatase (GTPase).²⁸ The Mimivirus genes can be classified into several groups including those composed by the core genes, the duplicated genes, the genes transferred horizontally, and the ORFans.²⁶ Several studies have attested that horizontal gene transfer (HGT) and gene duplication have contributed considerably to the gene content of Mimivirus.²⁶

GENOMIC-BASED CLASSIFICATION

Mimivirus has been classified within the group of NCLDV, on the basis of comparative genomics and the definition of genes shared by all the viruses and composing a core genome (Fig. 71.9).^{58,59} The NCLDV group was conceived in 2001 by Iyer et al.⁵⁸ Originally, it consisted of four families of viruses, *Poxviridae*, *Asfarviridae*, *Iridoviridae*, and *Phycodnaviridae*,

which share 9 genes (including three viral hallmark genes) found in all of the viral families (group I) and 22 additional genes found in at least 3 of the 4 viral families (group II and III) (Fig. 71.10). In 2006, Iyer et al.⁵⁹ examined the Mimivirus genome and several other genomes newly available for three of the previously defined NCLDV families, and they tentatively defined the gene complement of the ancestral NCLDV and found that it harbored at least 41 core genes. Finally, Yutin et al.¹⁴⁸ identified 1,445 NCLDV COGs, so-called NCVOGs, including 177 represented in more than one NCLDV family and 5 including proteins from all 45 analyzed viruses (Fig. 71.11).¹⁴⁸ Additionally, they used a maximum-likelihood reconstruction of the evolution of NCLDVs to define a set of 47 conserved genes that were probably present in the genome of the NCLDV common ancestor.

GENE REPERTOIRE

Core Genes. The core genes of the NCLDVs have been classified from the most to the least evolutionarily conserved, as class I when found in all lineages, as class II when missing in some species albeit being present in all lineages, and as class III when missing in one lineage (Fig. 71.10).¹¹³ The Mimivirus genome encodes homologs for the 9 NCLDV core genes of group I, for 6 out of 8 core genes of group II, and for 11 out of 14 core genes of group III (Fig. 71.12A).

Horizontally Transferred Genes. HGT refers to the exchange of genes between unrelated organisms and is a major factor of evolution in microbiology.^{50,60,65} Because of the high frequency

FIGURE 71.9. Phylogeny reconstruction of nucleocytoplasmic large DNA viruses based on four concatenated core genes. Bayesian phylogenetic tree was constructed from a cured concatenated alignment of four universal nucleocytoplasmic large DNA virus clusters of orthologous groups of proteins (NCVOGs) (496 conserved positions): primase-helicase (NCVOG0023), DNA polymerase (NCVOG0038), packaging adenosine triphosphatase (ATPase) (NCVOG0249), and A2L-like transcription factor (NCVOG0262). Bayesian posterior probabilities are mentioned near branches as a percentage and are used as confidence values of tree branches. Only probabilities at major nodes are shown. Scale bar represents the number of estimated changes per position for a unit of branch length. Other Mimivirus close relatives are among those cited in.⁷⁷ (Adapted from 25.)

of HGT, phylogenetic boundaries can be blurred in some cases.^{29,68} Regarding viruses, HGT has had a major impact on the shaping of the genomes of bacteriophages, and HGT between bacteriophages and their bacterial hosts is considered as a major engine of the evolution of bacteria.¹⁸ Among the proteins encoded by herpesviruses, which are also large DNA viruses, many are assumed to have been acquired from their host to mimic or block normal cellular functions.^{86,87,93}

Ogata et al¹⁰³ found that among the 363 Mimivirus ORFs that exhibit recognizable homologs in other organisms, 8.3% of ORFs likely originated from recent HGT. Later, Filée et al³⁶ reported unambiguously identifying 8.6% of the Mimivirus genes (78 of 96 bacterial-like genes) as having a bacterial origin. These genes of putative bacterial origin show a bias toward DNA replication and repair (20% protein) and cell envelope (12.5% protein) in COGs functional categories (Fig. 71.12D).³⁶ Filée et al³⁴ noticed that among NCLDV, only Mimivirus and *Chlorella* phycodnaviruses acquired more than 2% of their genes from bacteria, the highest proportion

being in Mimivirus. In contrast, the Mimivirus genome seems to contain the lowest proportion (0.8%) of genes acquired from the eukaryotic host among the NCLDVs, this proportion being about one-third to one-tenth of that observed in poxviruses. Moreira and Brochier-Armanet⁹⁴ specifically studied a set of 198 Mimivirus proteins that were previously assigned to COGs.¹¹³ Clear homologs were retrieved for 126 of these ORFs, and the most abundant sets of ORFs ($n = 47$ ORFs, 37%) were composed of ORFs present only in eukaryotes and bacteria, followed by ORFs present in all three domains ($n = 29$, 23%); 21 ORFs (17%) were found only in eukaryotes. Lastly, less than 10% of the 126 Mimivirus ORFs were found only in bacteria ($n = 12$), in bacteria and archaea ($n = 9$), and in archaea and eukaryotes ($n = 8$). Moreover, phylogenetic analysis inferred a eukaryotic, archaeal, bacterial, and viral origin for 60, 1, 29, and 4 of the 126 Mimivirus ORFs, respectively; approximately 10% of ORFs for which a eukaryotic origin was inferred appeared to be acquired from amoebae (Fig. 71.12D). A close phylogenetic relationship was identified

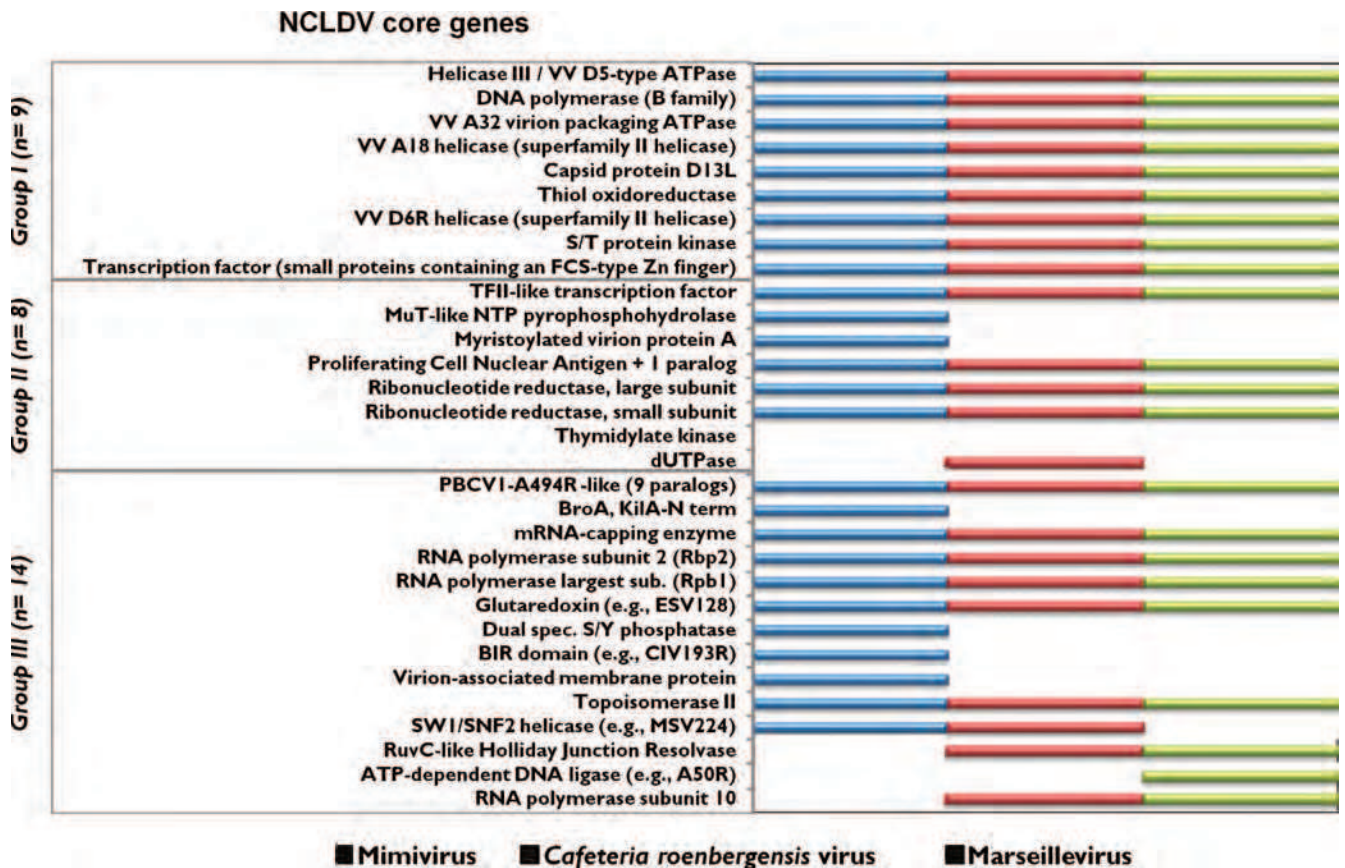

FIGURE 71.10. Presence/absence of NCLDV core genes of classes I, II, and III in the gene repertoire of Mimivirus, *Cafeteria roenbergensis virus*, and Marseillevirus.

for some Mimivirus ORFs with eukaryotes unrelated to the *Amoebozoa* that belong to the *Heterolobosea* (including *Nae-gleria*) and to the *Kinetoplastida* (comprising *Trypanosoma* and *Leishmania* as members). Noteworthy, Forterre⁴² reviewed phylogenies reported by Moreira and Brochier-Armanet⁹⁴ and did not agree with their interpretation. Indeed, he concluded that 32, 34, and 21 Mimivirus proteins are of bacterial, eukaryotic, and viral origin, respectively, whereas Moreira and Brochier-Armanet concluded that 29, 60, and 4 Mimivirus proteins are of bacterial, eukaryotic, and viral origin, respectively (Fig. 71.12D). These differences highlight that inferring an origin for genes putatively involved in HGT can be tricky.

Filée et al³⁶ analyzed the distribution of bacteria-like genes in Mimivirus and identified three consecutive co-inherited ORFs encoding a transaminase sugar, a glycosyltransferase, and a protein of unknown function. The synteny for these three ORFs with genes in the *Clostridium acetobutylicum* genome suggests their transfer as a contiguous block. Moreover, Filée et al³⁶ noted that Mimivirus genes of putative bacterial origin tend to be positioned in the first and last 250 kilobases (kb) of the genome, whereas NCLDV core genes and genes of eukaryotic origin tend to be located in the central fragment of the genome. Remarkably, it was proposed for other larger eukaryotic DNA viruses that viral core genes inherited vertically might be located in the central segment of the genome, while genes

involved in HGT with cellular hosts or other viruses might be positioned at the extremities of the genome,¹²³ which were identified as highly recombinogenic regions in poxviruses.⁸⁸ In addition, Filée et al³⁶ detected numerous mobile genetic elements (MGEs) in the Mimivirus genome, although these were previously considered specific to prokaryotes. These MGEs include apparently intact insertion sequences (ISs), regarded as major agents of HGT in prokaryotes.⁴⁵ ISs have not been identified in another eukaryotic viral genome, except in the *Ectocarpus silicosus* virus 1 genome. Those detected in the Mimivirus genome seem to be full-length copies and belong to the IS607 family. They are embedded within areas of adjacent bacterial-like genes or ORFans, which supports their possible co-inheritance with bacterial genes. In addition, the Mimivirus genome contains numerous homing endonucleases, including two HNH homing endonucleases that are found principally in bacteriophage genomes.³⁶ Thus, HGT involving different sources appears to have fashioned substantially the genome of Mimivirus, as for some other NCLDVs.^{34,35,59} In contrast, NCLDVs with host cells that do not prey on bacteria, as algae or metazoa, contain a lower proportion of genes putatively acquired from bacteria in their genomes.^{34,110} This suggests that living sympatrically with bacteria in amoeba may provide a biological niche appropriate for the exchange of DNA. This concept is developed later specifically in another part of this

FIGURE 71.11. Distribution by functional categories of predicted proteins identified in protist-associated giant viruses that are homologous to the 177 nucleocytoplasmic large DNA virus clusters of orthologous groups of proteins (NCVOGs) found in at least 2 nucleocytoplasmic large DNA virus (NCLDV) families. (Data used for this figure are from Yutin N, Wolf YI, Raoult D, et al. Eukaryotic large nucleocytoplasmic DNA viruses: clusters of orthologous genes and reconstruction of viral genome evolution. *Virology* 2009;6:223.)

chapter (Ecology of Giant Viruses Associated With Phagocytic Protists: Amoebae as Genitors and Reservoirs of Giant Viruses). The remarkably extensive and diverse gene content of amoeba-associated giant viruses may provide them several benefits. For instance, *Legionella pneumophila* has acquired by HGT eukaryotic genes involved in a variety of cell functions, including two serine/threonine protein kinases,¹⁶ which have been shown to inhibit phagosome–lysosome fusion in several pathogens.¹³⁸ It was hypothesized that three serine/threonine protein kinases and a Ras GTPase identified in the Mimivirus genome could be involved into the regulation of the amoeba cycle by Mimivirus.⁹⁴

Duplicated Genes. Genome and gene duplication lead to the emergence of new genes.^{56,150} Duplicated genes can diverge considerably; they can lose their functionality and degenerate into pseudogenes, or alternatively, they can evolve toward sub- or neo-functionalization. Suhre¹²⁶ determined that both genome and gene duplications have contributed importantly to the structure and large size of the Mimivirus genome. Mimivirus appears to be the NCLDV member with the greatest proportion of duplicated genes in its gene repertoire, this proportion being lower than 15% for most of the other NCLDVs.³⁴ First, Suhre

reported data that suggested the occurrence of a segmental duplication involving a ~200,000-nt-long 5' end fragment of the Mimivirus genome; this duplication may have been followed by a rearrangement around the center of the chromosome fraction. Second, Suhre determined that about one-third of the Mimivirus genome consists of duplicated genes (from 26% to 35% of its genes, depending on whether the e-value cutoff for PSI-BLAST search is 10^{-25} or 10^{-10} , respectively) (Fig. 71.12A). This rate is of the same order of magnitude as frequencies determined for members of the *Archaea*, *Bacteria*, and *Eukarya* domains of life.¹²⁶ Suhre also showed that a log-linear correlation exists for Mimivirus and other DNA viruses between the number of predicted genes and the number of paralogs in the genome. Regarding Mimivirus, the maximum number of duplications is 11. Duplicated genes are inserted about two times more frequently in parallel orientation (in reference to the coding direction of the matching ORF) as in antiparallel orientation. In addition, they are not evenly distributed along the genome: 79% of those in *cis* orientation compared to 39% of those in *trans* orientation are located in the same half of the genome. Among the largest paralogous gene families, several display homology with proteins that may play a role in interactions between the Mimivirus and its

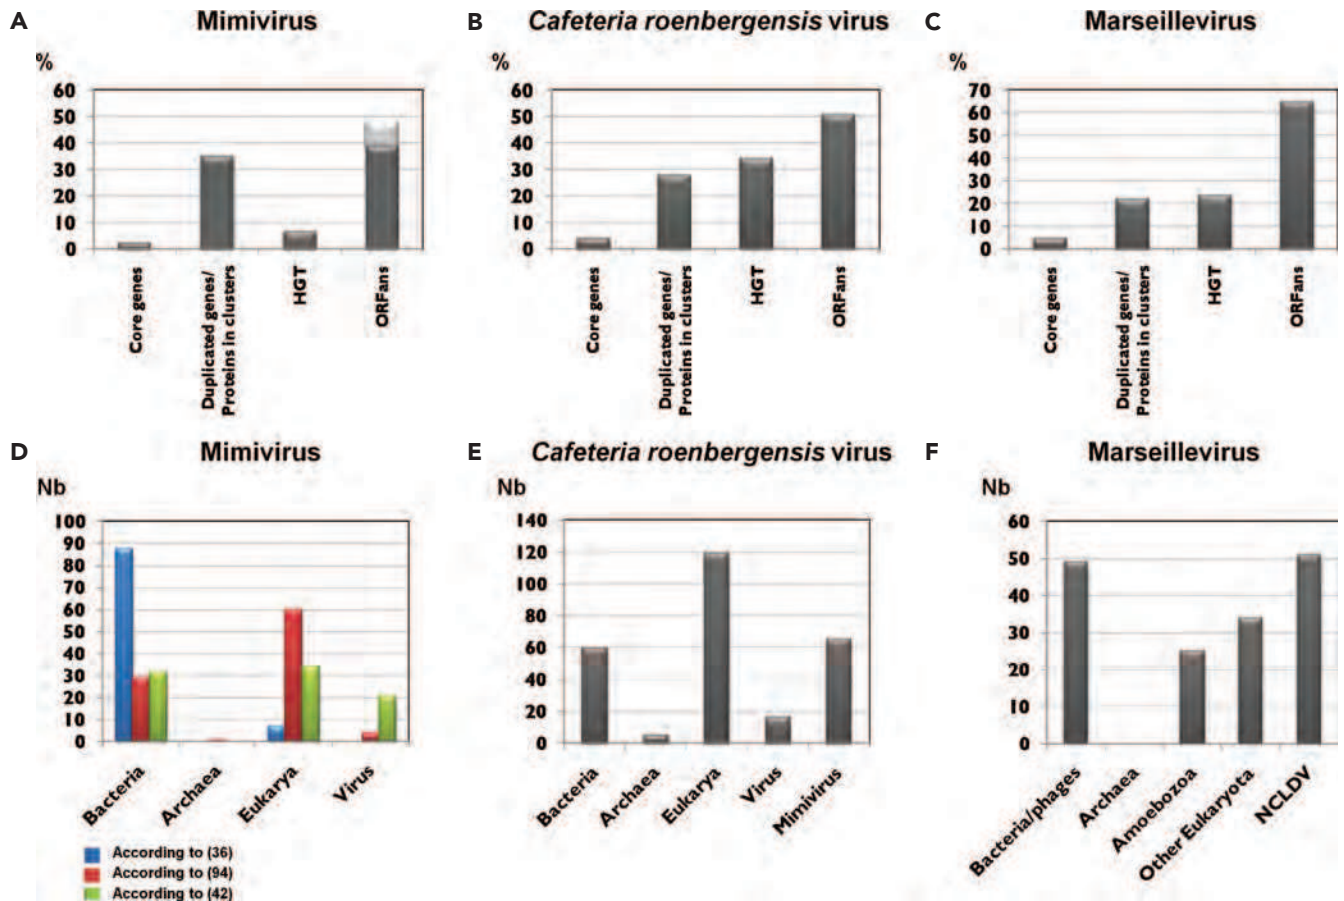

FIGURE 71.12. Distribution of open reading frames (ORFs) identified in the genomes of Mimivirus (A,D), *Cafeteria roenbergensis* virus (B,E), and Marseillevirus (C,F), according to categories of genes (A–C) or inferred origin (D–F).

amoebal host. The largest paralogous gene family is composed by ankyrin repeat-containing proteins, which mediate protein–protein interactions.⁸³ The second-largest family is composed of predicted proteins of unknown function with the BTB/POZ domain that mediates homo- or heterodimeric dimerization. Another family of paralogs includes proteins with several FNIP repeats; an N-terminal domain matches the Pfam F-box domain that is a receptor for ubiquitination targets, while several ubiquitin-conjugating enzymes are concurrently detected in the Mimivirus genome. Another paralogous family is composed of proteins with collagen triple helix repeats.

ORFans. ORFans refer to genes that lack homolog in a sequence database.³⁸ This means that when a BLAST search is performed against all sequence databases, those genes were not found in any other organism. As a comparison, it was recently assessed that the proportion of ORFans among the NCLDV genomes varied considerably, ranging from 2.8% for *Paramecium bursaria chlorella* virus NY-2A (PBCV-NY2A) to 75.2% for *Emiliana huxleyi* virus 86 (EhV-86)¹³; besides, this proportion was ~30% and ~9% in viral and bacterial genomes, respectively.³⁸ In Mimivirus, the number of ORFans was 474 (48.1% of the gene repertoire) when determined against the National Center for Biotechnology Information (NCBI) RefSeq protein sequence database (Fig. 71.12A). Among these ORFs, 63 (6.9% of the whole gene repertoire) were defined

as meta-ORFans, because they were found to have the closest matches to environmental sequences.¹³

Mimivirus Specific Genes. A remarkable and unexpected feature of the Mimivirus gene repertoire was the identification of several predicted proteins associated with protein synthesis. Indeed, viruses are known as devoid of such genes and as obliged to rely on the host cell protein translation apparatus.¹¹⁴ Before the Mimivirus discovery, tRNA-like genes were known to exist in dsDNA viruses including bacteriophages, herpes virus 4, or chlorella viruses, and an elongation factor gene was also found in chlorella viruses.¹¹³ However, the Mimivirus expanded considerably the set of viral genes associated with protein translation.¹¹³ Indeed, the identification of four amino acyl-tRNA synthetases (a cysteinyl-, an arginyl-, a tyrosyl-, and a methionyl-tRNA synthetase; messenger RNA (mRNA) encoding the three first proteins are packaged within the viral particle), a tRNA-modifying enzyme, three translation initiation factors (4E, SUI1, IF-4A), and a peptide release factor (eRF1) were unique to the Mimivirus. Moreover, several findings indicated that these proteins may have an important role in viral protein translation and assembly. In addition, six tRNA-like genes were identified. Also, an unusual and large set of genes encoding homologous proteins to enzymes involved in different repair pathways of DNA damages due to oxidation, methylation, alkylation, UV light, and nucleotide mismatch

was identified. These genes include some never described before in dsDNA viruses: two encoding formamidopyrimidine-DNA glycosylase, a UV-damage endonuclease, a 6-O-methylguanine DNA methyltransferase, and a protein that belongs to the MutS protein family associated with DNA mismatch repair and recombination. Mimivirus is also the first virus with a gene encoding a topoisomerase IA; additionally, genes encoding topoisomerases IB and IIA, previously found in NCLDV, are also present in the Mimivirus genome. Thus, topoisomerases of type IA, IIA, and IIB are concurrently encoded by Mimivirus genes, which is rarely encountered among microorganisms.¹¹³ Besides, two Mimivirus genes uniquely encode chaperones of the HSP70 family, and three other ORFs encode proteins with a DnaJ domain that associate with HSP70 family proteins. Mimivirus is also the first virus to encode a putative peptidyl-prolyl *cis-trans* isomerase of the cyclophilin family, which accelerates protein folding. As with other large dsDNA viruses, the Mimivirus genome has genes involved in various metabolic pathways such as nucleotide synthesis, amino acid metabolism, lipid metabolism, and polysaccharide metabolism. Among these proteins, some are unique in viruses, especially those intervening in the glutamine metabolism. In addition, glycosyltransferases that may be involved in posttranslational modifications of proteins were detected.

Intein and Introns. An intein has been detected in the family B DNA polymerase of Mimivirus.^{105,113} Inteins are segments of proteins that catalyze self-splicing at the protein level. Mimivirus is one of the few eukaryotic viruses that has been found to harbor an intein, and this intein is most likely to be functional.^{105,130} In addition, six introns were identified in the Mimivirus genome, one in the DNA-directed RNA polymerase (II) subunit 1, three in the DNA-directed RNA polymerase subunit 2, and two in the MCP.^{2,113} Proteomic analysis showed that intron in the β -subunit of the RNA polymerase is excised.¹¹⁷

ADDITIONAL FEATURES

The Mimivirus genes can be classified as early, intermediate, and late according to three major temporal classes of expression, as determined by mRNA deep sequencing.⁸¹ An early promoter (AAAATTGA sequence, unique to Mimivirus) found in front of 74% of the Mimivirus ORFs classified in the early class versus 6% of those classified in the late class, and late promoters found in 24% of the genes classified in the late class versus less than 3.5% of those classified in the early or intermediate classes were successively predicted.^{81,127} In addition, Mimivirus genes were found to be expressed as polyadenylated transcripts.¹⁷ A large majority (greater than 80%) of the analyzed mature mRNA 3' ends were found to contain palindromic sequences promoting the perfect pairing of 13 or more successive nucleotides into hairpin-like structures. The nature and the stringency of the hairpin rule defining the location of polyadenylation sites in Mimivirus mRNA are unique to this virus; in addition, this signal appears to be absent in the amoebal host.¹⁷

The codon usage of Mimivirus and its amoebal host, *Acanthamoeba* spp., is almost the opposite.¹¹³ Indeed, the proteome of Mimivirus exhibits a substantial positive bias for residues encoded by AT-rich codons, with isoleucine, asparagine, and tyrosine, for instance, being twice as frequent in Mimivirus as in *Acanthamoeba* proteins. Besides, it has been demonstrated that genome signatures of Mimivirus, and those of large viruses, tend to deviate from the genome signatures of their hosts.⁹⁸

MIMIVIRUS PROTEIN COMPONENTS

The composition of purified isolated virions by capillary liquid chromatography-tandem mass spectrometry LC-MS/MS, two-dimensional (2D) gel electrophoresis, and matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometry revealed that 137 proteins are packaged into the Mimivirus particles.^{22,117} The most abundant group of proteins associated with the Mimivirus particles is constituted by proteins of unknown function ($n = 65$ in first analysis), 69% of them being ORFans. Apart from this set of proteins, enzymes and factors involved in transcription compose the largest functional category of these proteins.¹¹⁷ They include four transcription factors, mRNA guanylyltransferase, two helicases, and the five subunits of a DNA-directed RNA polymerase. The third largest group of encapsidated proteins contains gene products associated with oxidative pathways. Other proteins are involved in protein/lipid modifications, DNA topology and repair, and particle structure, including the capsid protein and the major core protein. Further analysis of these proteomic data identified additional proteins including the B-type DNA polymerase and several ankyrin repeat-containing proteins as encapsidated into Mimivirus particles. A total of four among the nine class I core genes were detected in the virions, including the major capsid protein.²² Moreover, analysis of 2D gels suggested posttranslational modifications for proteins encapsidated within Mimivirus particles, including glycosylation and, possibly, cleavage and maturation.¹¹⁷

Besides, some of the Mimivirus proteins were expressed and their function was studied in some cases. The methionyl-tRNA synthetase and the tyrosyl-tRNA synthetase were expressed in *Escherichia coli* and their enzymatic function could be characterized.²² The function of other Mimivirus proteins was also studied, including that of a topoisomerase IB,⁷ a nicotinamide adenine dinucleotide (NAD⁺)-dependent DNA ligase,⁸ a mitochondrial carrier,⁹² human endonuclease VIII-like proteins,⁴ a nucleoside diphosphate kinase,⁶¹ a uridine 5'-diphosphate (UDP)-D-glucose-4,6-dehydratase, and a bifunctional UDP-4-keto-6-deoxy-D-glucose epimerase/reductase involved in L-rhamnose production.¹⁰⁷

Life Cycle

VIRAL ENTRY

Mimivirus is an obligate intracellular pathogen. It was initially isolated by culture on *Acanthamoeba polyphaga*, which was an efficient fortuitous strategy for the discovery of several amoebal pathogens.^{76,115} The virus can be propagated on *Acanthamoeba* spp., including *A. castellanii*, *A. polyphaga*, and *A. mauritanensis*. Several primary or established cell lines from invertebrate and vertebrate animals were tested for their ability to support Mimivirus infection and replication but without success.^{49,130} Thus, Mimivirus appears to have a narrow spectrum of host cells, which could indicate a high specificity for target cells. Otherwise, this virus would be able to propagate from amoeba to other eukaryotic cells.¹³⁰ However, Mimivirus is internalized by different professional phagocytes, including human myeloid cells, as circulating monocytes or monocyte-derived macrophages.⁴⁹

The 120- to 140-nm-long external fibrils may be involved in the attachment of Mimivirus to the amoeba. Specifically, the protein heads of the outer fibers are likely involved in the attachment of the virus to the surface of the amoeba.⁷⁵ Peptidoglycans present at the outer surface of Mimivirus particles may

promote phagocytosis by amoebae. In addition, amoebae are capable of phagocytosis of any particle larger than $0.5\ \mu\text{m}$, a size range that includes the giant Mimivirus.^{71,110} Ghigo et al.⁴⁹ demonstrated that Mimivirus enters the amoebal cell, which is a professional phagocyte, through phagocytosis, whereas this virus cannot enter nonprofessional phagocytes. Mimivirus is the first virus described to enter cells by canonical phagocytosis. Such a phagocytic-like process for entry of viruses into their host cell was previously only suggested for herpes simplex virus infection of fibroblasts, which are not professional phagocytes.²⁴ Ghigo et al.⁴⁹ studied Mimivirus uptake by macrophages and detected viral uptake after 1 to 2 hours using real-time polymerase chain reaction (PCR) with plaque-forming unit (PFU)-to-cell ratios ranging from 10:1 to 200:1; uptake plateaued after 8 hours and was maintained for 24 hours.⁴⁹ Notably, in these experiments conducted on RAW 264.7 macrophages, Mimivirus was cytopathogenic, and viral particles released by macrophages replicated within amoebae, indicating that a productive cycle of Mimivirus replication occurred. The engulfment of Mimiviral particles requires F-actin but does not occur through macropinocytosis.⁴⁹ Protrusions of the cytoplasmic membrane at the virus entry site were demonstrated by F-actin labeling and ultrastructural analysis. Mimivirus activates phosphatidylinositol kinases (PIK3) and downstream phagocytosis effectors. Dynamin-II was shown to promote phagosome formation by membrane extension during the engulfment of the viral

particle. In contrast, neither clathrin-dependant endocytic routes nor degradative endosome-mediated endocytosis was found to be involved in Mimivirus entry mechanisms in these experiments. Involvement of a caveolin-independent lipid raft mechanism could not be excluded. Strikingly, cellular events associated with Mimivirus internalization are very similar when observed in macrophages and in amoebae.^{49,129} This observation is congruent with the knowledge that several microorganisms, including *Legionella pneumophila*, *Parachlamydia*, *Coxiella burnetii*, and *Cryptococcus neoformans*, are resistant to amoebae and macrophage pathogens.^{49,52,124}

VIRAL FACTORY AND RELEASE OF THE PROGENY

In the initial description by La Scola et al.⁷⁶ of the Mimivirus replication cycle using confocal microscopy and Mimivirus-specific monoclonal antibodies, rare phagocytized Mimivirus particles were detected within the amoeba cytoplasm at $T = 0$ hour. Then, an eclipse phase, typical of a viral replication cycle, occurred and no particle was visible at $T = 4$ hours. At $T = 8$ hours, Mimivirus particles appeared within amoebae while an increasing number of amoeba cells were infected with Mimivirus. Finally, at $T = 20$ hours, viral particles were seen in ghost amoebae (Figs. 71.13, 71.14, and 71.15). The localization of the Mimivirus replication cycle has been debated. Suzan-Monti and colleagues^{129,130} observations indicate that Mimivirus DNA might be transported to the nucleus following viral

FIGURE 71.13. Schematic representing the Mimivirus replication cycle.

FIGURE 71.14. Electron microscopy of different stages of Mimivirus replication in *Acanthamoeba*. **A:** Hour (H) 0 postinfection. **B:** H3 postinfection. **C–E:** H6 postinfection. **F, G:** H12 postinfection. **H:** H16 postinfection. **D, E, and G** show the Mimivirus factory. **A–C, F:** Scale bars indicate 5 μm . **D, E, H:** Scale bars indicate 2 μm . **G:** Scale bar indicates 200 nm.

decapsidation, while the experiments by Mutsafi et al¹⁰⁰ suggest that the Mimivirus replication cycle occurs exclusively in the cytoplasm. In the study conducted by Suzan-Monti et al,¹²⁹ Mimivirus could be observed following entry into the amoeba within phagocytic vacuoles. Empty particles with an opened vertex were seen at this stage, with several viruses present in the same vacuole in some cases. At 4 hours postinfection, the internal viral membrane extrudes, sheds the viral DNA genome, and fuses with the membrane of the phagocytic vacuole, while outer Mimivirus structures remain intact. Subsequently, a cytoplasmic viral factory (VF) appears and is surrounded by mitochondria. VFs are structural and functional elements associated with the replication of nucleic acids and with a massive production of virions.¹⁰² Compared to the VFs observed for other viruses, Mimivirus VFs display some similarities and major differences, including with that of other NCLDV.¹²⁹ Notably, no membrane surrounds the Mimivirus VF. Around 5 hours postinfection, the cytoplasmic area occupied by the nuclei decreases by 50%, while the cytoplasmic viral factory area increases by 50%. Then, between 5 and 8 hours postinfection, the cytoplasmic VF increases in size, and new viral particles can be observed at its periphery at the end of this period. Thereafter, the VF continues to expand to occupy an estimated area of 250 μm^2 at 12 hours postinfection, representing ~42% of the amoebal cytoplasmic surface. Most of the infected amoebae are lysed at 24 hours postinfection, and amoebal lysis represents the most probable mode of virion release. Otherwise, the absence of an outer

membrane suggests that Mimivirus exit from amoeba does not occur via budding at the cytoplasmic membrane.¹³⁰ Notably, Mimivirus appears to have a very rapid lytic effect on amoebae, more rapid than that observed for other amoebae-resistant pathogens.⁵² Three zones were described by Suzan-Monti et al¹²⁹ within the cytoplasmic VFs of Mimivirus: an inner heterogeneous structure with dense inclusions, which corresponds to the replication center, where condensation of the viral DNA appears to initiate; an intermediate zone where viral assembly is thought to occur; and a peripheral zone where new viral particles gain their outer fibrils. From the center to the outside, capsid shells are assembled and then filled with DNA through an open portal (Figs. 71.15 and 71.16). Suzan-Monti et al¹²⁹ studied the localization of Mimivirus DNA and the kinetics of the VF and viral DNA formation using direct fluorescent staining with diamidino-2-phenylindole (DAPI), which preferentially stains dsDNA with a high AT proportion.¹²⁹ Overall, the total fluorescence intensity within the cell increased sevenfold between 0 and 8 hours postinfection, which represents a doubling time of 2.7 hours. Viral replication appeared to be composed of two successive phases with distinct localizations: from 0 through 3 hours postinfection, the mean fluorescence intensity statistically significantly increases in the nucleus; then, from 4 through 8 hours postinfection, the mean fluorescence intensity significantly increases within the cytoplasmic VF. Stained DNA dots are seen in the amoeba nucleus at 1 hour postinfection, and at 4 hours postinfection, a heterogeneous

FIGURE 71.15. **A:** Electron microscopy of Mimivirus replication in *Acanthamoeba*. **B, C:** Details of a Mimivirus factory surrounded by newly formed viral particles at 12 hours postinfection of amoebae. Scale bars indicate 2 (**A**), 1 (**B**), and 0.5 (**C**) μm .

structure appears outside of the nucleus, which corresponds to the formation of the core of the cytoplasmic VF. This core becomes homogeneous between 4 and 12 hours postinfection, while viral production is observed from 7 hours postinfection. Finally, the VF reaches a heterogeneous degenerative stage. Taken together, these observations led to the proposal that Mimivirus DNA first enters into the nucleus of infected amoebae, possibly for a first round of replication, and then the Mimivirus DNA exits from the nucleus and moves to the cell

cytoplasm. At 3 hours postinfection, the viral DNA forms the replication center of a cytoplasmic VF, which is the major site of the DNA genome replication.¹²⁹

Mutsaers et al¹⁰⁰ used diverse imaging techniques and proposed a different scenario than Suzan-Monti and colleagues for the replication cycle of Mimivirus, which is entirely cytoplasmic, as demonstrated for poxviruses. These authors claim that this scenario is compatible with difficulties that may be encountered for the transport of the huge viral DNA

FIGURE 71.16. Electron microscopy of Mimivirus factory and newly formed Mimivirus particles in an amoeba 12 hours postinfection. Scale bars indicate 1 μm .

genome into the nucleus then back into the cytoplasm. According to Mutsafi et al, Mimivirus particles are detected within amoebal phagosomes at 2 hours postinfection, and free spherical particles and spheres surrounded by replicating DNA are seen at 2 to 3 hours postinfection. The genome release is accompanied by DNA decondensation and the initiation of massive DNA replication. In addition, early transcription appears to initiate in the viral cores during DNA release and shortly after their exit from Mimivirus particles.¹⁰⁰ Then, the newly synthesized mRNAs accumulate at discrete cytoplasmic sites adjacent to but in close opposition to DNA replication sites. Notably, according to the observations of these authors, each Mimivirus core seeds one replication factory at the site where the viral DNA genome is released. Subsequently, fusion of several expanding VFs can eventually occur, which may lead to a single VF at the late stage of infection.^{100,149} In this scenario, replication is not necessarily entirely independent of the amoebal nucleus because it may involve nuclear factors as previously shown for the vaccinia virus.^{100,106} Viral proteins may be partially or fully synthesized or grouped in the replication center, while no cellular host proteins seem to be incorporated into the virus particles, as demonstrated by proteomics.¹¹⁷ It remains largely unknown if and by which mechanisms cellular gene expression is modulated and the cell machinery is used to participate in the formation of Mimivirus virion progeny.

DNA RELEASE AND PACKAGING

The star-shaped structure, which was designated as the stargate by Zauberman et al,¹⁴⁹ is suspected to mediate a large-scale opening in the capsid that allows the protrusion of the inner membrane of the Mimivirus. Using AFM, Kuznetsov et al⁷⁵ observed that the arms of the stargate detach from the viral particle, allowing the five triangular faces of the capsid underneath to open outward with the icosahedral edges folding as hinges (Fig. 71.5). This event is thought to precede the fusion of the viral membrane sac with the phagosomal membranes, promoting the formation of a membrane tube for the release of the viral genome. Thus, it was proposed that the DNA genome may be released into the amoebal cytoplasm enclosed within a vesicle. Such a process would allow the long Mimivirus genome to be translocated across the amoebal host cytoplasm and to be protected against nucleases. In addition, Zauberman et al¹⁴⁹ observed multiple lysosomes undergoing fusion with the phagosomes, and they hypothesized that these lysosomes possibly act to open the viral capsid. Renesto et al¹¹⁷ hypothesized that the lipolytic and proteolytic enzymes encapsidated in the Mimivirus particles may act to allow the virus to access the amoebal cytoplasm. Thereafter, ejection of the Mimivirus DNA from the viral particle, DNA repair, and early transcription may be mediated by the two topoisomerases, IA and IB, and the DNA repair machinery components. The presence of immediate early gene transcripts is suggested by the detection in the virions of transcripts encoding three of the core genes (including the DNA polymerase, the capsid protein, and the TFII-like transcription factor), three of the four amino-acyl tRNA synthetases, and four ORFan genes.¹³⁰ These transcripts may be required for the first steps of the Mimivirus replicative cycle. According to Zauberman et al,¹⁴⁹ Mimivirus DNA packaging into procapsids appears to occur at a vertex or, alternatively, through an opening located at an icosahedral face in

~60% of observations and that spans the outer and inner capsid shells and the internal membrane, as assessed by electron tomography and volume reconstruction analysis.¹⁴⁹ The aperture is cone shaped and has a diameter of 35 nm at the outer shell and of 25 nm at the inner shell. This opening is sealed after the completion of DNA packaging into Mimivirus capsids (Fig. 71.3). However, no evidence was found in other studies that an alternate portal exists for DNA packaging, and observations have led to the hypothesis that the Mimivirus DNA may be released and incorporated into the viral capsid by the starfish-shaped aperture.

DNA REPLICATION

The mechanism of Mimivirus DNA replication is unknown. The Mimivirus DNA may assume a circular shape, as deduced from the existence of an inverted repetition of a sequence that is ~600 nucleotides in length at both extremities of the linear dsDNA genome (at positions 22,515 and 1,180,529 of the chromosome, respectively).^{22,113} This repeated inverted sequence may allow DNA to take a Q shape with a short and a long tail.¹¹³ Notably, the ~22,500-nt-long region that may constitute the long tail region harbors a set of seven genes encoding proteins involved in DNA replication and binding.²² An origin of DNA replication is hypothesized to be located near position 400,000 based on a slope reversal of the cumulative A+C excess along the genome.¹¹³ Indeed, such a sequence bias has been related to the location of the origin of replication in bacteria.⁴³ Nevertheless, this hypothesis remains uncertain for Mimivirus.

TRANSCRIPTION OF MIMIVIRUS GENES

The transcriptional activity of Mimivirus genes was studied using deep mRNA sequencing and provides additional hints to the aforementioned structural analysis to elucidate the Mimivirus replication cycle.⁸¹ At $T = -15$ minutes of infection, ~90% of the transcripts correspond to *Acanthamoeba* genes. At $T = 0$, more than 50% of transcripts correspond to Mimivirus genes, while ~50% of the host transcripts correspond to mitochondrial genes. At $T = 1.5$ hours, Mimivirus transcripts decrease to ~50% of the transcriptional activity, and after T is greater than 3 hours, they become predominant. Three major patterns are observed in the transcriptional activity of Mimivirus-infected amoebae, each accounting for one-third of this activity: from the entry of Mimivirus to $T = 3$ hours, from $T = 3$ to 6 hours, and from $T = 6$ through 12 hours. Mimivirus transcripts detected during these three periods are classified as early, intermediate, and late, respectively, and this classification is congruent with that obtained using hierarchical clustering and with the presence of early or late promoters.^{81,127} Nonetheless, substantial variability can be observed within each of the three classes regarding the level of transcriptional activity and its timing. Early-expressed Mimivirus genes are enriched with genes of unknown function and include three of the four amino-acyl tRNA synthetases. Interestingly, hypothetical proteins represent 85% of the most abundant transcripts and are particularly abundant in the class of early expressed genes suspected to be critical for the replication cycle. Intermediate Mimivirus genes include a large proportion of genes involved in DNA replication. Finally, late-expressed genes comprised genes involved in the structure of the viral particle, including the MCP. In addition, most of the genes encoding the transcription apparatus belong to this class, and their abundance peaks at $T = 6$ hours. All but one of these proteins are

found within the virions.^{22,117} Most of the genes involved in the biosynthesis of the outer layer of the viral particle and in some of the posttranslational protein modifications are also expressed after T = 6 hours. Regarding the component of the translation apparatus, most are expressed at a medium or high level and exhibit an early or late expression pattern.⁸¹

Acanthamoeba Castellanii Mamavirus

The existence of another strain of Mimivirus was first reported in 2008 by La Scola et al.⁷⁸ This virus was named Mamavirus due to initial observations suggesting a particle size slightly larger than that of Mimivirus. However, both giant viruses were later shown to be phenotypically indiscernible. Of note, the sputnik virophage was discovered in amoebal cultures co-infected with Mamavirus (Fig. 71.6).⁷⁸ *Acanthamoeba castellanii mamavirus* was recovered by inoculating *Acanthamoeba* culture with water collected from a cooling tower in Paris, France. The Mamavirus genome was revealed to be larger (by ~10,000 nt) than that of Mimivirus; it is 1,191,693 nt in length (Table 71.1; Fig. 71.7A).^{28,78} In addition, this genome harbors 1,023 predicted protein-coding genes, which are evenly distributed on the direct and reverse DNA strands (Fig. 71.7B). Besides, 30 non-coding RNAs and the 6 same tRNAs found in the Mimivirus genome were identified.²⁸ A total of 879 Mamavirus protein-coding genes were identified as *bona fide* orthologous genes to Mimivirus genes, the mean amino acid identity being 98.3% for those genes. Seven orthologs have different positions in the Mamavirus and Mimivirus genomes. Overall, the two genomes are highly similar with ~99% nucleotide identity in their alignable regions, which represent nearly the entire length of these genomes. Notably, the Mamavirus genome has an extra 5' terminal fragment that is ~13,000 nt in length and contains disrupted duplicated genes. Conversely, Mimivirus contains a 3' terminal segment that is ~900 nt in length and has no counterpart in Mamavirus. In total, 75 ORFs are differentially present in the Mamavirus versus Mimivirus genome; 29 Mimivirus ORFs and 46 Mamavirus ORFs are partially or completely missing in the counterpart genome. A small regulatory subunit of polyA polymerase is present only in Mamavirus; homologs for this predicted protein could be only identified in some unicellular eukaryotes and in poxviruses.

Cafeteria Roenbergensis Virus

In 2011, the genome of a giant virus recovered from the coastal waters of Texas in the 1990s was described. This virus, with a 300-nm-diameter capsid, was named *Cafeteria roenbergensis* virus (CroV) because it infects a marine heterotrophic flagellate, *Cafeteria roenbergensis*, a phagotrophic protist that grazes on bacteria and viruses and is widespread in marine environments (Table 71.1).³⁹

CroV has a linear dsDNA genome that is ~730 kb in length; the portion of the chromosome that was sequenced was 618 kb with flanking regions described as highly repetitive (Fig. 71.7A). The genome is AT rich with 77% A+T content. CroV appears to be a *bona fide* Mimiviridae member based on the analysis of its DNA polymerase B and phylogeny reconstruction from four universal NCVOGs (primase-helicase, DNA polymerase, packaging adenosine triphosphatase [ATPase], and A2L-like transcription factor).^{25,39}

A total of 544 putative protein-coding sequences have been predicted in the 618-kb sequenced segment of the CroV

chromosome; coding capacity is 90.1% (Fig. 71.7A). In addition to the nine NCLDV core genes of class I, five and nine NCLDV core genes of classes II and III, respectively, are present (Fig. 71.7B). Among the predicted ORFs, 267 (49%) display significant similarities to sequences in the NCBI GenBank database (Fig. 71.12B), while 134 (23%) have been assigned to 1 or more COGs. A putative function can be assigned to 32% of the ORFs, and some of these have never previously been reported in viruses. Proteins involved in DNA replication, recombination, and repair are the most highly represented (37 ORFs), followed by those involved in posttranslational modifications and protein turnover and classified as chaperones (27 ORFs); those involved in transcription (17 ORFs); and those involved in translation, ribosome structure, and biogenesis (13 ORFs). Fischer et al.³⁹ found that at least 172 CroV genes belong to an NCVOG, while 32% of the CroV genes display significant similarity with a Mimivirus gene (Fig. 71.11).³⁹ The distribution of top BLASTp hits against the NCBI nonredundant database for the 544 ORFs demonstrates affiliation with eukaryotes in 22% of cases, bacteria in 11% of cases, archaea in 1% of cases, Mimivirus in 12% of cases, other viruses in 3% of cases, and no hits for 51% of the ORFs (Fig. 71.12E). Paralogous genes are more frequent at the ends of the genome.²⁵ Several ORFs are predicted to be involved in protein synthesis, including an isoleucyl-tRNA synthetase, putative homologs of eukaryotic translation initiation factors, and two tRNA-modifying enzymes. In addition, 22 tRNA genes have been identified, which are clustered around position 510,000 in the genome in a 2.8-kb segment. Other proteins are involved in DNA repair, including some associated with DNA mismatch repair and alkylated DNA repair and others composing a complete base excision repair pathway as well as two photolyases. One of the photolyases is the first viral homolog identified for a class I photolyase, and the second is a homolog of a Mimivirus sequence. CroV also harbors numerous ORFs encoding transcriptional machinery, including a protein highly similar to an ELP3-like histone acetyltransferase that has not been previously identified in viruses and that may modulate the genome condensation state or be involved in the replication and packaging of the CroV genome. In addition, three DNA topoisomerases of types IA, IB, and IIA were identified. Besides, 51% of the CroV ORFs are ORFans, as they found no significant hit against the NCBI nonredundant database.³⁹

A 22-amino acid-long leucine-rich repeat, similar to the FNIP/IP22 repeat and also found in Mimivirus, was detected in at least 28 ORFs and is present with greater than 400 copies in the CroV chromosome. Overall, ~5% of the CroV genome corresponds to repetitive elements. Additionally, several genes are predicted to encode proteins of the ubiquitin pathway, which may represent a defense strategy against hosts in NCLDVs. Strikingly, a 38-kb genomic fragment was identified within the CroV genome between positions 264,800 and 302,500 that is highly AT rich (80.6% A+T) and contains no early or late promoters that have been identified within the other parts of the genome. This region is proposed to be the result of large-scale HGT from bacteria (Fig. 71.12B). It is composed of 34 ORFs, among which 14 are most related to bacterial proteins. Some genes are predicted to encode sugar-modifying enzymes, including glycosyltransferases, while others may be involved in carbohydrate metabolism, including enzymes for the biosynthesis of 3-deoxy-D-manno-octulosonate (KDO), which is

NCBI, National Center for Biotechnology Information.

an essential component of the lipopolysaccharide layer (LPS). Thus, this protein links lipid A to polysaccharides in gram-negative bacteria.¹⁰⁹ Four ORFs also contain an intein. One of these inteins is the only previously reported from a virus in the DNA-dependant RNA polymerase II subunit 2 with that found in the *Emiliana huxleyi* virus 163; another intein is the unique case detected in a DNA topoisomerase gene. A perfectly or nearly perfectly conserved motif (AAAAATTGA) was identified as an early promoter for 23% to 35% of the ORFs ($n = 127$ to 191); this motif is highly similar to that found in Mimivirus (AAAATTGA). In addition, a putative late promoter was identified for 124 genes classified as “late,” but this late promoter is not related to that described in Mimivirus.⁸¹ Microarray analysis revealed that 63% of studied genes are expressed, though it has been hypothesized that nearly all CroV genes are expressed. In experiments by Fischer et al.,³⁹ CroV gene expression comprised an early phase (0 to 3 hours postinfection) and a late phase (6 hours postinfection or later). Most of the predicted proteins involved in DNA replication and transcription belong to the early class, whereas predicted structural proteins belong to the late class.

MARSEILLEVIRIDAE

Marseillevirus

Marseillevirus has been isolated by co-cultivating *A. polyphaga* with water collected in 2007 from a cooling tower in Paris, France.¹⁵ This virus has an icosahedral shape and a diameter of ~250 nm (Fig. 71.17; Table 71.1). The capsid shell has a thickness of ~10 nm, and 12-nm-long fibers with globular ends are present at the viral surface. A membrane may surround the nucleocapsid, which is separated from the capsid shell by a gap of ~52 nm. It has been observed in amoebal culture that Marseillevirus enters the amoeba 30 to 60 minutes postinfection. Later, a VF appears close to the nucleus of the amoeba. Capsid assembly and viral genome encapsidation

are observed simultaneously in these VFs, leading to mature and immature Marseillevirus particles. The replication cycle is complete 5 hours postinfection, which is a short period of time. Additionally, the morphology of the host cell nucleus changes considerably between 30 minutes and 2.5 hours postinfection, which suggests that the replication cycle may involve the nucleus.¹²⁹

Marseillevirus was classified within the NCLDV group based on the finding of all group I core genes from this grouping (Fig. 71.10). The Marseillevirus genome is a circular, dsDNA molecule that is 368,454 bp in length (Fig. 71.7A). The Marseillevirus genome, with a G+C content of 44.7%, is less AT rich than that of *Mimiviridae*. A total of 457 ORFs are predicted to encode proteins whose sizes range from 50 to 1,537 amino acids (Fig. 71.7B). The coding sequence represents 89.3% of the chromosome. The ORFs are evenly distributed on the positive and negative strands (224 and 233, respectively). Significant matches with sequence databases were obtained and/or conserved domains were identified for 188 proteins, which represent 41% of the putative genes. In addition, significant similarity was found for 163 ORFs by searching the Global Ocean Survey (GOS) environmental database. As in other NCLDVs, the proportion of the Marseillevirus gene content that belongs to the NCLDVs' core gene set is very low (4.8%). Indeed, 22 ORFs belong to the 31 previously defined NCLDV class I to III core gene sets (Fig. 71.10).⁵⁸ Additionally, six Marseillevirus ORFs correspond to universal NCLDV proteins, and 17 are shared with Mimivirus/Mamavirus (though they are absent in the other NCLDVs). Phylogenetic analysis based on universal NCLDV proteins indicates that Marseillevirus represents the first member of a new putative viral family of NCLDVs, the *Marseilleviridae*. Among the NCLDVs, Marseillevirus branches deeply with iridoviruses/ascoviruses.^{15,148} In contrast, comparison of the NCLDV gene repertoires groups Marseillevirus with Mimivirus and Mamavirus. Besides, 17 proteins were identified as present in Mimivirus but absent in other NCLDVs.¹⁵

FIGURE 71.17. Electron microscopy of Marseillevirus particles. A, B (detail of A): Transmission electron microscopy images of Marseillevirus particles in the cytoplasm of an infected amoeba. C: A negative staining electron microscopy image of a Marseillevirus particle. Scale bars indicate 200 nm.

The analysis of the *Marseillevirus* genome highlighted its mosaicism and the role of amoeba as an opportune biological niche for gene acquisition and exchange between sympatric bacteria, viruses, and their amoebal hosts (Fig. 71.12C, F).¹⁵ Thus, the findings of Boyer et al¹⁵ indicate that numerous *Marseillevirus* ORFs were derived through HGT from many different sources. Among the *Marseillevirus* gene content, 59, 57, 70, and 2 predicted proteins exhibit the highest sequence similarity to viral, bacterial, eukaryotic, and archaeal homologs, respectively. Among the 80 *Marseillevirus* ORFs with putative amoebal homologs, the ORF that has the closest similarity to the *Marseillevirus* ORF is from *Acanthamoeba* in eight cases. On the basis of phylogenetic analyses, the *Marseillevirus* genome contains 51 genes (11%) of probable NCLDV origin, 49 (11%) of probable bacterial or bacteriophage origin, and 85 (19%) of probable eukaryotic origin. For 22 proteins, a phylogenetic relationship encompasses Mimivirus, *Marseillevirus*, and *Acanthamoeba*. Notably, in several cases, it was inferred by Boyer et al¹⁵ that related genes were likely acquired from independent sources by Mimivirus and *Marseillevirus*, suggesting that HGT may be a common event. Additionally, origins inferred for the *Marseillevirus* proteins display a tendency for being related to their function. Thus, bacterial or bacteriophage origin is inferred for many of the proteins involved in defense and repair, including nucleases. Eukaryotic and bacterial origins are inferred for many proteins involved in metabolic functions and lipid modification or degradation. Finally, eukaryotic origin is inferred primarily for proteins involved in signal transduction.

Comparative analysis of the *Marseillevirus* protein sequences identified 28 clusters of proteins representing a total of 121 proteins (22% of the ORFs).¹⁵ The largest protein family is composed of 20 proteins containing bacterial-like membrane occupation and recognition nexus (MORN) repeat domains; these domains are described to mediate membrane–membrane or membrane–cytoskeleton interactions.⁵³ Three predicted *Marseillevirus* proteins are homologous to histone-like proteins not previously identified in NCLDVs, and they have been detected in the viral particle, suggesting that they may be involved in condensation of the viral DNA before it is packaged. Additionally, the *Marseillevirus* genome carries the largest number of serine/threonine protein kinases for a virus ($n = 15$) and a large set of ubiquitin system proteins, which suggests an important potential for signaling. In addition, 20 proteins are involved in interactions between membranes or with the cytoskeleton, and 10 encode bacteriophage HNH endonucleases and restriction-like endonucleases that typically reside in mobile selfish genetic elements. A total of 49 proteins were identified in purified virions. These proteins comprise NCLDV core proteins, including the capsid protein; proteins likely involved in the early steps of viral replication (e.g., an early transcription factor); and other structural proteins. Ten of the 49 proteins were glycosylated, and 19 were phosphorylated, indicating posttranslational modification of *Marseillevirus* proteins. In addition, as for Mimivirus, several *Marseillevirus* RNAs are likely packaged within *Marseillevirus* particles, including transcripts encoding the capsid protein, DNA polymerase, D6R helicase, and TFII-like transcription factor.

Lausannevirus

Lausannevirus was isolated using amoebal co-culture from freshwater collected in 2005 from the Seine River, France.¹³³

When cultured on amoebae, viral particles were observed 30 minutes postinfection, and then an eclipse phase occurred that lasted until 2 hours postinfection. Vesicles filled with viruses and viral particles free in the cytoplasm are observed from 4 hours postinfection. Viruses fill all amoebae at 8 hours postinfection, and amoebal lysis is observed 16 hours postinfection. The Lausannevirus host range appears to be restricted to *Acanthamoeba* spp.

Lausannevirus is a close relative of *Marseillevirus* and can be classified within the putative family *Marseilleviridae*. The Lausannevirus genome is 346,754 bp in length and has a G+C content of 42.9% (Table 71.1).¹³³ It is either a linear DNA molecule with terminal repeats or a circular molecule. This genome harbors 450 ORFs that cover 93% of the genome and have a mean length of 716 bp. A total of 332 proteins (73.8% of the putative proteome) display significant similarity to proteins in the NCBI nonredundant sequence database, among which 320 (71.1%) have a *Marseillevirus* protein as the best BLASTp hit. Homologs were identified in Lausannevirus for all NCLDV core genes detected in *Marseillevirus*. Notably, the comparison of the Lausannevirus genome to that of *Marseillevirus* shows a 150-kb region with poor synteny that is enriched in hypothetical proteins followed by a 200-kb region with a higher co-linearity and slight enrichment for NCLDV core genes. The largest viral families in Lausannevirus correspond to MORN repeat-containing proteins, endonucleases, and serine/threonine protein kinases. As in *Marseillevirus*, three histone-like proteins were identified in Lausannevirus, which may form histone doublets, be functional, and be involved in interactions with the viral DNA. Additionally, Thomas et al¹³³ reported that a deoxyuridine triphosphate nucleotidohydrolase (dUTPase) is present but truncated in *Marseillevirus*, but it is nearly complete in Lausannevirus. In addition, differences were underscored regarding the presence or absence of blocks composing an endonuclease domain within the ribonucleotide reductase intein present in Lausannevirus and *Marseillevirus*.

VIROPHAGES: VIRUSES INFECTING MIMIVIRIDAE

Definition

The virophage concept was coined in 2008 by La Scola et al⁷⁸ when reporting the discovery of icosahedral viral particles 50 nm in size in the amoebal cytoplasm of infected cells and inside the Mamaviruses factories (Figs. 71.6 and 71.18).⁷⁸ This small virus, named Sputnik, can only multiply within *Acanthamoeba* spp. co-infected with Mamavirus or Mimivirus. Indeed, Sputnik and the giant virus both replicate in the VF, but differences were noted regarding the location and kinetics of their replication. Sputnik is produced earlier than Mamavirus, while co-infection with Sputnik and Mamavirus is associated with a 70% decrease in the yield of infective Mamavirus and a threefold decrease in lysis of *Acanthamoeba*, as assessed 1 day postinfection. Concurrently, a significant increase in the production of Mamavirus virions with morphological anomalies is observed (Fig. 71.6C, D), which includes an increase in the capsid thickness (in 11% of virions instead of 1% in the absence of Sputnik co-infection) that reached sixfold the usual thickness in some viral particles. Besides, Sputnik was observed in a small fraction of the Mamavirus particles (Fig. 71.6B). Taken together, these observations indicate that

FIGURE 71.18. Electron microscopy of viral factories during co-infection of *Acanthamoeba* with Mamavirus and Sputnik (at 16 hours after infection). Solid arrows show Sputnik particles; dashed arrows show Mamavirus particles. **A** and **B** represent two different magnifications. Scale bars indicate 1 μm .

Sputnik considerably affects the replicating cycle of its host virus and highlight functional analogies for Sputnik with bacteriophages, which led to the name virophage. Sputnik appears as a virophage rather than a satellite virus. Thus, in addition to the aforementioned features, it was not observed in the absence of Mamavirus or Mimivirus and requires these giant viruses for its replication. In addition, the replicative cycle of Sputnik occurs entirely within the viral factory of these giant viruses, no signal having been detected within the amoebal nucleus.³¹ Sputnik particles were usually observed at one side of VFs in the absence of Mamavirus/Mimivirus particles, or both viruses were seen separately at different sides of the VFs.³¹ Moreover, 16 Mimivirus-like putative hairpin structures in the Sputnik genome, which were recently found to correspond to polyadenylation signals and specifically used by the Mimivirus-encoded transcription machinery, were identified in the Sputnik genome; thus, their presence suggests the late expression of Sputnik genes in Mimivirus VFs and coincides with the rarity of the AAAATTGA early Mimivirus promoter.^{17,21,127}

The existence of virophages was confirmed in 2011 by the identification of Mavirus, a virophage infecting CroV.⁴⁰ Moreover, a third virophage, named Organic Lake virophage (OLV), which preys on viruses infecting phototrophic algae, was recovered from Organic Lake, a hypersaline meromictic lake in Antarctica, and described in 2011. The detection of another virophage associated with a Mimivirus-like virus was reported by La Scola et al.⁷⁷ These findings suggest that virophages may be common in ecological niches of protist-associated giant viruses.

Sputnik

The Sputnik particle is ~ 74 nm (71 to 84 nm according to symmetry axis) in size (Figs. 71.6 and 71.18).¹²⁸ Its structure was analyzed by cryo-EM three-dimensional reconstruction. The major capsid protein is organized into a hexagonal lattice, the triangulation number being 27. The capsomer structure is trimeric. The thickness of pseudohexameric capsomers is

~ 7.5 nm, and the distance between the centers of adjacent capsomers is ~ 7.5 nm. Mushroom-like fibers are present at the surface. They may help to stabilize capsomers or may be involved in entry into host cells; they may be flexible. These fibers are 5.5 nm in length, have a triangular head, and protrude from the center of pseudohexameric but not pentameric capsomers. Instead, centers of pentameric capsomers harbor a cavity that may represent a gate for DNA release or packaging, as in bacteriophages. The major capsid protein of Sputnik is likely to have a double jelly-roll fold as in viruses of the PRD-1-adenovirus lineage, and the crystal structure of PBCV-1 MCP was fitted into the cryo-EM map of Sputnik.¹²⁸ Notwithstanding, no sequence similarity was found for the MCP, neither with that of these latter viruses nor with the Mimivirus MCP. Besides, Sputnik and Mimivirus MCP have a similar length (595 vs. 591 amino acids, respectively). The capsid shell surrounds two layers, likely a lipid bilayer, which have a total thickness of 4 nm and may harbor a transmembrane protein. Around 2.5 nm underneath this putative membrane is the packaged DNA; its packaging density is ~ 1.966 angstrom³/bp. In proteomic analyses, the Sputnik ORF20, which corresponds to the putative capsid protein, was the most abundant; two other minor virion proteins (ORF 8 and 19) were concurrently detected.

Sputnik has a circular dsDNA genome that is 18,343 bp in size with an organization that is typical of viral genomes, that is, with a tight ORF arrangement (Table 71.1).⁷⁸ This genome is AT rich (73%) as observed in mimiviruses. The Sputnik genome was likely not integrated into the Mamavirus genome; noteworthy, no read was found that overlapped both genomes. A total of 21 genes predicted to encode proteins of 88 to 779 amino acids were identified. Among them, 14 are ORFans, whereas the 7 remaining ORFs have various putative origins including eukaryotic, bacterial, viral or plasmid, and environmental origins (Fig. 71.19). Sputnik appears an unknown family of viruses based on comparative analyses. Thus, the Sputnik DNA is a particularly chimerical genome, which suggests its involvement in HGT. Furthermore, such

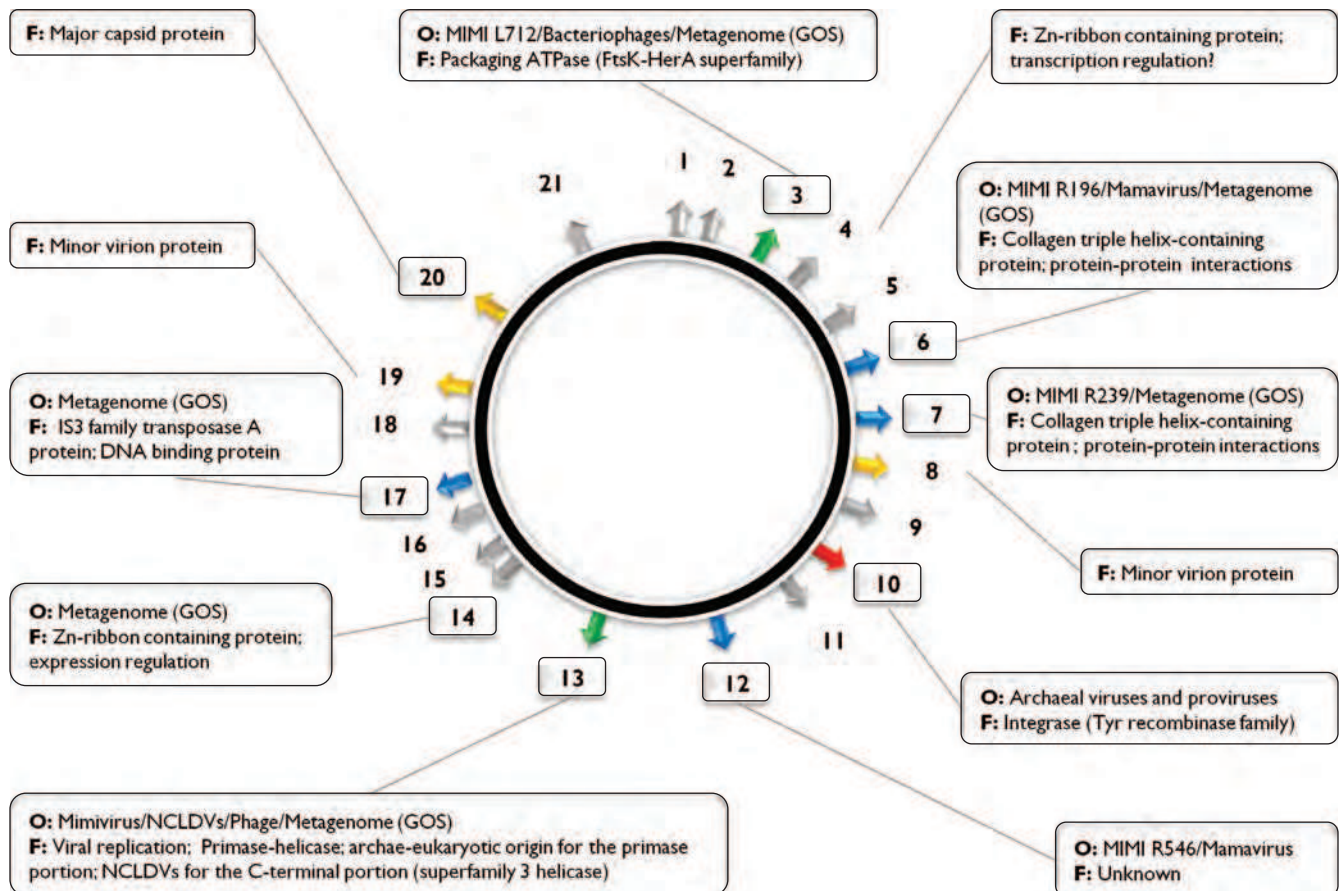

FIGURE 71.19. Sputnik genome annotation. Sputnik open reading frames (ORFs) are represented by their number; F, predictive function, activity, protein family; O, closest homolog in the National Center for Biotechnology Information (NCBI) GenBank protein sequence database (nr) or the Global Ocean Survey (GOS) data set, putative origin.

a chimeric gene repertoire and the presence of putative integrase and transposase led to the hypothesis that this virophage might represent a vehicle of genes. Noteworthy, viral RNAs corresponding to all but one Sputnik ORF (ORF 17) were detected inside the Sputnik virions; nevertheless, this ORF was detected together with all other ORFs at 4 hours postinfection during the replication cycle.³¹

Sputnik might adhere to Mamavirus/Mimivirus fibrils, which would allow its entry into amoeba, in the same endocytic vacuole as Mamavirus/Mimivirus.³¹ Sputnik has been indeed frequently observed in association with or trapped inside the surface fibers of Mamavirus.³¹ In addition, Sputnik replication was not detected during co-infection with Marseillevirus, which is devoid of fibers, and with a bald form of Mimivirus.¹² Mimivirus protein R135 might be involved in the adhesion of Sputnik to Mimivirus/Mamavirus because it is one of the three proteins recently detected by two-dimensional gel electrophoresis and MALDI-TOF mass spectrometry from purified Mimivirus fibers,¹² and this protein was also identified from purified Sputnik particles.⁷⁸

Mavirus

A virophage, named Mavirus (for Maverick virus), was identified in association with the recently described CroV.⁴⁰ As

Sputnik, it reduces host cell lysis and production of its associated giant virus, in the absence of which it is not able to replicate. Viral particle size is about 60 nm. Mavirus has a 19,063-bp circular dsDNA genome, with an A+T content of 69.7% (Table 71.1). This genome was predicted to encode for 20 proteins. A nearly perfect inverted repeat of ~50 bp, which may adopt a hairpin structure with a 15-nt loop, was identified between ORFs 20 and 1. The mean size of Mavirus ORFs is 883 nucleotides, corresponding to a coding density of 92.6%; a conserved promoter motif located in the intergenic region and that resembles a CroV putative late promoter motif was found to precede all 20 ORFs. This finding suggests that Mavirus gene expression is ruled by the CroV transcription apparatus during the late stages of its replication cycle.

Similar genome length and structure and a close evolutionary relationship were highlighted by Fischer and Suttle⁴⁰ between Mavirus and the self-synthesizing *Maverick* or *Polinton* transposable elements (MP TEs), a type of DNA transposons with a length of 9 to 22 kb that encode up to 20 proteins. Mavirus and MP TEs share indeed seven homologous proteins, including a rve-superfamily retroviral integrase that harbors a conserved chromo domain, which was found to be duplicated in several chromatin-binding proteins and may be associated with positive or negative regulation of transcription,⁷⁰ and

a protein-primed DNA polymerase B; the highest similarity for these two genes was found with sequences from the *Polysphondylium pallidum* genome. In addition, a superfamily 3 helicase and the MCP predicted in Mavirus were found sporadically encoded by MP TEs. Besides, four Mavirus predicted proteins (20% of the gene content) have homologs in Sputnik: these putative proteins are a capsid protein, a DNA-pumping ATPase, a cysteine protease, and a GIY-YIG endonuclease/Zn ribbon containing protein. On the basis of aforementioned data, Fischer and Suttle hypothesized that MP TEs may derive from a Mavirus ancestor; alternatively, but less likely, an escaped MP TE may be at the origin of Mavirus. Moreover, Mavirus was highlighted to increase the survival of *Cafeteria roenbergensis*, the host for this virophage and the giant CroV. This suggests that Mavirus might confer a selective advantage to the cell population suffering from CroV infection. This is potentially true for all virophages and was recently emphasized for OLV, a third virophage found to control dynamics of antarctic algal host-virus populations.¹⁴⁷

EPIDEMIOLOGY OF GIANT VIRUSES ASSOCIATED WITH PHAGOCYtic PROTISTS

To date, the epidemiology of giant viruses associated with phagocytic protists and their virophages is largely unknown. A growing body of data indicate that mimiviruses and marseilleviruses may be ubiquitous in the biosphere. Regarding direct evidence through viral isolation, Mimivirus and Mamavirus were notably recovered in two different countries, the United Kingdom and France, respectively, from water collected in cooling towers.^{76,78} In addition, CroV was recovered in the United States in marine water from a different host than that of the two former viruses. Indeed, *Cafeteria roenbergensis* is a heterotrophic dinoflagellate that is widespread in marine water and belongs to the *Chromalveolata*, a phylum that is phylogenetically distant from *Acanthamoeba* spp., which are the hosts of mimiviruses and marseilleviruses.³⁹ Interestingly, viruses may regulate populations of *C. roenbergensis*.⁸⁵ Moreover, 19 other giant viruses, whose capsid sizes range from 150 to 600 nm, have been recovered from various water and soil samples using culture on amoebae.⁷⁷ Among these viruses, at least five were related to mimiviruses by means of phylogenetic analysis of the B-family DNA polymerase and MALDI-TOF mass spectrometry. Strikingly, these 19 giant viruses were recovered by inoculating 105 environmental samples using modified protocols for amoebal culture, which corresponds to a ~20% isolation yield. Recently, Mimivirus-like particles were retrospectively observed by light microscopy within *Acanthamoeba* spp. in final-stage conventionally treated sewage sludge from a wastewater treatment plant in the West Midlands, United Kingdom.⁴⁷ The infected *Acanthamoeba* spp. culture could not be resuscitated, and only sewage sludge samples collected later were tested for Mimivirus by PCR with negative results. Nonetheless, the initial observation of a high density of viral-like particles suggests that *Acanthamoeba* spp. that survive sewage treatment can disseminate Mimivirus- or other giant virus-infected amoeba to agricultural land and surface waters.

Additionally, bioinformatic analyses performed on metagenomes recovered from marine samples suggest that microalgae and modern sponges might be hosts for unidentified members

of the family *Mimiviridae*.^{48,91,120} Indeed, sequences similar to those of Mimivirus were identified in databases of sequences recovered from water samples collected in the Sargasso Sea and during the GOS (Global Ocean Sampling) expedition. Regarding this latter study, DNA polymerase fragments corresponding to Mimivirus relatives were the most frequently recovered sequences in 86% of sample sites, after those of bacteriophages. Kristensen et al.⁷² also found hits for Mimivirus sequences against marine metagenomes. In addition, two sequences from a viral metagenome library from water recovered 200 m deep in Monterey Bay, California, were recently found to have a BLAST hit with Mimivirus.¹²⁵ Regardless, the results of these metagenomic analyses should be interpreted with caution with respect to the question of the prevalence of giant viruses. Thus, since Ivanovsky's experiment, viruses have not been considered to be visible by light microscopy.¹¹⁵ This paradigm has led to a considerable bias in recent studies of viral metagenomics, which have filtered the samples prior to analysis.^{1,33,134} Such procedures inevitably prevent the detection of viruses larger than the pores of the filters used (i.e., 0.2 to 0.45 μm).^{32,134,141,151}

ECOLOGY OF GIANT VIRUSES WITH A SYMPATRIC LIFESTYLE IN PHAGOCYtic PROTISTS: AMOEBAE AS GENITORS OF GIANT VIRUSES WITH MOSAIC GENE REPERTOIRES

The tremendous size and composition of giant viruses that infect protists has led to a fundamental revision of our vision of viruses and has been linked to their sympatric lifestyle, consisting of their replication and survival in a community with other viruses and bacteria (Fig. 71.20).¹¹⁰ Despite differences in their epidemiology and host, it is notable to observe several common features for the genomic organization of mimiviruses and marseilleviruses.²⁵ Thus, comparative genomics of the currently identified giant viruses of protists underscores a substantial level of plasticity and various origins of their gene content, in accordance with the recently proposed theory that the evolution of life resembles the shape of a rhizome more so than a tree.¹¹¹ Overall, the genomes of giant viruses are mosaics containing genes of eukaryotic, bacterial, and/or archaeal origin and are substantially reshaped by horizontal gene transfer, by gene duplications, and possibly through recombination.^{15,36,94,126} The lifestyle of giant viruses, replicating and surviving in phagocytic protists, likely explains the remarkable diversity of origins for their repertoire of genes, as these phagocytic protists are genitors of chimeric viruses.^{15,39,110} *Acanthamoeba* spp., the host cells of Mimivirus, Mamavirus, Marseillevirus, and Lausannevirus, are free-living amoebae that are ubiquitous in the environment, including the air, soil, and water,¹¹⁹ as well as wild phagocytes that ingest any particle greater than 0.5 μm .¹¹⁰ They harbor, transiently or for long periods, a variety of intracellular bacteria, including *Proteobacteria*, *Firmicutes*, *Chlamydia*, *Bacteroidetes*, and *Actinobacteria*, as well as giant viruses.^{55,110} *Cafeteria roenbergensis*, the CroV host, and *Acanthamoeba polyphaga* and *castellanii* are phylogenetically distantly related, but *Cafeteria roenbergensis* feeds on bacteria and viruses.^{39,85} Giant viruses infecting phagotrophic protists live sympatrically within their host cell with numerous other bacteria and

FIGURE 71.20. Schematic of the sympatric lifestyle of giant viruses in phagocytic protists. B, bacteria; C.E.O., capsid-encoding organism; E, eukaryota; GV, giant viruses; N, nucleus; R.E.O., ribosome-encoding organism; VF, viral factory; Vp, virophage. Dashed arrows represent gene transfers.

viruses, which enables them to exchange genes. As an illustration, *Legionella drancourtii*, a *Parachlamydia* strain, and Marseillevirus were observed concurrently within *A. castellanii* following experimental co-infection.¹⁵ Phagocytic protists may even become ribo-viro cells, where genes from ribosome-encoding organisms (REOs) or capsid-encoding organisms (CEOs) can be exchanged, possibly including exchange by virophages when they are present (Fig. 71.20).^{15,42,78,114} Thus, gene foraging by such bacteria and viruses with a sympatric lifestyle is possible due to the promiscuity between their replicating genomes and that of their host. As an illustration, two Mimivirus proteins, corresponding to a Zn-dependent alcohol dehydrogenase and an outer membrane lipoprotein, seem to have homologs in common amoebal inhabitants, *Legionella pneumophila* and *Campylobacter* spp., respectively.⁹⁴ In such arenas as phagocytic protistan grazers, viruses and bacteria must struggle for life, and they may require a tremendous gene armory to resist their phagocytic host and outcompete or at least survive in competition with other viruses and bacteria.¹¹⁰ In contrast, for other obligate intracellular bacteria that live allopatrically in other eukaryotic cells, the capacity to acquire foreign

genes is limited. It has been noted that obligate intra-amoebal parasites (i.e., bacteria and viruses) exhibit larger genomes than their intracellular relatives,¹¹⁰ including some in which genome reduction was described.¹²¹ A statistically significant correlation was found between lifestyle and genome size for NCLDV; having a sympatric lifestyle is positively correlated with carrying a larger genome.¹¹⁰ For instance, the *Legionella drancourtii* genome is larger than that sequenced from *Legionella pneumophila* strains,¹⁰⁴ and the genome of *Rickettsia bellii* is the largest among *Rickettsia* species.⁹⁰ Among the NCLDVs, mimiviruses have the largest genomes.¹¹⁰ Strikingly, a relationship between genome size and sympatric lifestyle was shown experimentally for Mimivirus. Thus, subculturing this virus 150 times in a germ-free amoebal host was associated with a dramatic reduction of its genome (~16%).¹² Interestingly, in this study, the gene loss was associated with the emergence of phenotypically different viruses that lacked surface fibers and whose VFs differed morphologically compared to wild-type viruses.

One possible mechanism for HGT between viral and bacterial genomes within phagocytic protists may involve

recombination. Filée et al³⁶ hypothesized that gene acquisition in Mimivirus may resemble recombination-primed replication processes that have been described in the bacteriophage T4⁹⁷ and that allow the introduction of foreign DNA by a splice or patch mechanism. Filée et al also underscored the high frequency of homologous recombination during the replication cycle of poxviruses with the requirement of low-sequence identity^{139,146} and in phycodnaviruses.¹³² Processes allowing strand exchange, such as those observed in phage lambda, *Escherichia coli*, or herpesviruses, which can occur in the absence of replication and involve a DNA-binding protein and an exonuclease, may represent another mechanism for DNA exchange.^{36,101,118} Alternatively, it has been proposed that recombination may be promoted by an enzyme similar to the topoisomerase IB of vaccinia virus. Indeed, a DNA topoisomerase IB encoded by the Mimivirus genome has been described and characterized.^{7,36}

PATHOGENICITY

Acanthamoeba can infect a large spectrum of mammals, including humans,⁸⁹ and have been considered as “Trojan horses”.⁵ Most of the bacteria that survive and multiply in amoebae are indeed human pathogens.⁵² The question of the Mimivirus pathogenicity has focused initially on the capability of this virus to cause pneumonia. Indeed, water-associated bacteria that are amoebae-resistant pathogens are involved in both community- and hospital-acquired pneumonia.⁷⁹ In addition, pneumonia remains undiagnosed in 20% to 50% of cases, and the spectrum of causative agents in pneumonia is incompletely recognized.^{27,79} Six clinical studies have assessed whether Mimivirus is associated with pneumonia, and the results are summarized in Table 71.2. In these studies, either serology or PCR was used, with serology being the most commonly used strategy, to search for indirect evidence of Mimivirus infections.

Overall, several findings argue for Mimivirus pathogenicity in humans or mice. Mimivirus is capable of infecting macrophages through phagocytosis, similar to what can be observed in *Acanthamoeba* spp., and infection leads to productive replication.⁴⁹ This may represent a pathway to pathogenicity. Alternatively, the outstanding Mimivirus genome size and gene armory suggests a possible adaptation to an extended range of hosts.²⁶ Nevertheless, Mimivirus does not efficiently replicate in co-culture with any other mammalian cells.¹¹⁵ Additionally, Mimivirus induces pneumonia in experimentally inoculated mice.⁶³ In all pneumonic mice, Mimivirus was cultured from the lung tissues, Mimivirus antigens were detected in the lung tissues, or both.⁶³ In humans, seroconversion to Mimivirus was observed in several patients presenting with pneumonia.⁷⁹ In addition, seroprevalence to Mimivirus was significantly higher in pneumonia patients than in controls,⁷⁹ the presence of antibodies to Mimivirus was associated with a poorer outcome in mechanically ventilated patients in intensive care units,¹³⁶ and rehospitalization after discharge was significantly associated with antibodies to Mimivirus.⁷⁹ Moreover, Mimivirus serology was positive in a patient with pneumonia and comprised reactivities against 23 different specific Mimivirus proteins, including 4 without known homologs.¹¹⁶ Nevertheless, cross-reactivities may explain some of the positive serologies to Mimivirus.¹⁰⁸

Studies have failed to isolate Mimivirus from patients with pneumonia. Furthermore, Mimivirus DNA could be amplified from a single patient with unexplained pneumonia.⁷⁹ The absence of additional cases of Mimivirus DNA amplification from patients presenting pneumonia may be related to infection with mimiviruses genetic variants.¹³⁷ Notably, one sample from a pediatric patient suffering from acute diarrhea was found to contain five sequence reads that displayed 47% to 52% amino acid identity to endonuclease genes in Mimivirus, but these sequences also possessed nearly similar levels of identity to bacterial and phage genomes, and phylogenetic analysis did not identify their precise origin.³⁷ However, Senegalvirus, a new giant virus associated with amoebae and that is a close relative to Marseillevirus, was recently identified in the feces from a young, healthy Senegalese man, which represents the first isolation of such a giant virus isolated from a human (GenBank accession no. HQ008533.1, HQ008532.1, HQ008531.1).

LABORATORY DIAGNOSIS

To date, diagnostic tools that aim to identify giant viruses associated with protists or their virophages in clinical samples have only been developed by a few teams and targeted the Mimivirus. Serological testing has been developed and implemented in the lab where this virus was discovered.²⁷ Seroprevalence studies were conducted to test the association of pneumonia with Mimivirus infections (Table 71.2). Cross-reactivity with other antigens besides the Mimivirus proteins was identified.¹⁰⁸ PCR assays have also been described by two teams for the detection of Mimivirus DNA in clinical respiratory samples.¹³⁷ In recent studies based on alignment of partial genomic sequences, it has been demonstrated that molecular diagnosis of Mimivirus or other giant viruses of protists should likely deal with the potential genetic diversity of these viruses.^{27,30,137} The recent and ongoing discovery of additional mimiviruses, marseilleviruses, and virophages confirms that considerable genetic diversity exists between viruses included within the same family. In addition, the gene content can vary substantially.^{15,39,78} Nonetheless, the availability of these new genomes might be influential for the design of more reliable molecular tests. Recently, La Scola et al⁷⁷ tentatively characterized giant viruses recovered from amoebal cultures using MALDI-TOF mass spectrometry.⁷⁷ This technology provided congruent results with the phylogenetic analysis of the B-family DNA polymerase (DNA PolB) and is a promising method to enable the preliminary identification and characterization of giant viruses associated with amoebae. Additionally, EM remains a powerful tool for the diagnosis of various giant viruses.

PREVENTION AND CONTROL

The question of the prevention and control of infections with protist-associated giant viruses may be considered premature because, at the present time, no pathology is strongly associated with them. However, it should be noted that culture of these large viruses has underscored their high resistance to several chemical compounds and physical treatments, and their sensitivity to antimicrobials is largely unknown. In addition, their intra-amoebal lifestyle may protect them from various agents.

TABLE 71.2 Summary of Clinical Studies that Have Tested Pneumonia Patients for Mimivirus Infections

Reference	Year(s) of sample	Country	Population size	Subgroup size	Main characteristics of patients	Respiratory sample types	Serology	PCR
La Scola et al, 2005 ⁷⁹	1985–1997	Canada	887	121	Adults; ambulatory/community-acquired pneumonia patients, Nova Scotia	N.t.	36 positive (9.7%)	N.t.
				255	Adults; hospitalized patients for community-acquired pneumonia, multiple centers across Canada			
				511	Adults; healthy control subjects, Nova Scotia	N.t.		
	2003–2004	France	129	32	Adults; ICU-acquired pneumonia patients, 1-year survey	BAL	5 positive samples out of 26 (19.2%) All negative	1 positive sample out of 32 (3.1%) N.t.
				50	Adults; controls (patients tested for anti- <i>Rickettsia</i> spp. antibodies)	N.t.		
				21	Adults; intubated control patients in ICU who did not present pneumonia	BAL		
Berger et al, 2006 ¹⁰	2003	France	157		Adults; ICU pneumonia patients (pneumonia was community acquired or ventilator associated)	N.t.	7 cases with high level of evidence and 7 additional cases with low level of evidence Positive	N.t.
Raoult et al, 2006 ¹¹⁶	2004	France	1		38-year-old laboratory technician	N.t.		N.t.
Vincent et al, 2009 ¹³⁶	2006–2008	France	300		Adults; ventilated patients in ICU with a suspicion of a ventilator-associated pneumonia and a positive serology for Mimivirus (cases)	N.t.	59 positive (19.7%)	N.t.
Larcher et al, 2006 ⁸⁰	2005–2006	Austria	214		Children hospitalized for respiratory tract infections; 209 nonimmunocompromised; 6-month survey during fall and winter seasons	NP aspirate samples	N.t.	All negative
Dare et al, 2008 ³⁰	2000–2001	Urban US	496	124	Children <5 years old; community-acquired pneumonia cases	Nasal swabs	N.t.	All negative
	2003–2004	Rural Thailand		120	Adults, children; community-acquired pneumonia cases	NP swabs	N.t.	All negative
	2002–2004	US		71	Geriatric; nosocomially acquired pneumonia outbreak, retirement centers	Nasal or oro-/NP swabs	N.t.	All negative
		US		5	Adults, children; community-acquired pneumonia outbreak (familial cluster)	Lower respiratory samples	N.t.	All negative
	2001–2003	US		87	Adults; bone marrow transplant recipients	NP aspirates, nasal wash, or NP swabs	N.t.	All negative
	2002–2003	Canada		89	Adults; lung transplant recipients	NP swabs	N.t.	All negative

N.t., not tested; BAL, bronchoalveolar lavage; NP, nasopharyngeal.

Thus, based on current knowledge, it is reasonable that Mimivirus and its relatives should be considered as biosafety class 2 pathogens. Notably, the case of a technical worker was reported who manipulated high titers of Mimivirus and later presented pneumonia and seroconversion to this virus without other identified causes for his clinical symptoms.¹¹⁶

GIANT VIRUSES ASSOCIATED WITH PROTISTS CHALLENGE THE DEFINITION OF VIRUSES AND LEAD TO PROPOSAL OF THE FOURTH DOMAIN THEORY

Giant viruses infecting phagocytic protists differ in many aspects from other canonical viruses and strongly challenge the vision of viral entities conveyed by Lwoff's classification.⁸⁴ Mimiviruses, the largest giant viruses to date, have a capsid diameter of ~500 nm, which is not in accordance with the historical concept of viruses as small, ultra-filterable entities.^{6,114,115} In addition, mimiviruses have large genomes that encode more than 1,000 predicted proteins.¹¹³ Moreover, Mimivirus was shown to harbor mRNA,^{113,117} which contradicts the criteria of Lwoff's⁸⁴ viral classification that viruses only possess one type of nucleic acid. Besides, the mimiviruses genomes encode proteins involved in translation, which represents a unique feature among viruses; they also encode tRNAs. Likewise, mimiviruses can themselves be infected by viruses. This was initially described by La Scola et al.,⁷⁸ who coined the name virophage, with Mamavirus,⁷⁸ and three years later by Fischer et al.³⁹ with CroV.

In addition to revealing unique features for viruses, the genomes of mimiviruses and marseilleviruses have been very influential in considering giant viruses as possible major ancestors in the early stages of the evolution of life.^{14,42,69,113,114,148} Viruses have been excluded from the tripartite putative tree of life composed of *Eukarya*, *Bacteria*, and *Archaea* because they lack ribosomes and, more generally, genes shared with members of these three canonical domains. The hypothesis that Mimivirus may compose a fourth domain of life was therefore groundbreaking.¹¹³ This assumption relies on the phylogeny of some of the Mimivirus genes that are shared with members of the three canonical domains of life. Two genes, which encode the tyrosyl tRNA synthetase (TyrRS) and the universal DNA replication clamp loader protein (RFC), have been particularly analyzed, and the interpretation of their phylogeny has fostered discussion about whether or not Mimivirus and, more generally, the NCLDV as a whole constitute a new branch in the tree of life. Some consider that the branching of Mimivirus as a domain on its own is an artifact.^{23,42,67,95,96,112–114} A major point of discussion is that horizontal gene transfer and nonorthologous gene displacements that occurred during the evolution of NCLDVs might considerably impair phylogenetic reconstructions.^{29,68,148} Furthermore, the interpretation of tree topologies may be complicated because there is no evidence of the viral ancestors that may have infected extinct proto-eukaryotes.¹⁹

Besides, it was pointed out that some interpretations of tree topologies suggesting the absence of a fourth domain might have been influenced by the paradigm that viruses are gene robbers and have acquired many of their genes from the

three cellular domains.⁴² Thus, when reinterpreting the phylogeny reconstructions of Moreira and Brochier-Armanet,⁹⁴ Forterre⁴² concluded that 32 instead of 60 Mimivirus proteins have a putative eukaryotic origin, and 21 instead of 4 proteins have a putative viral origin. In 2010, Boyer et al.¹⁴ performed a phylogenetic analysis of genes involved in nucleotide metabolism and DNA processing, which are present in cellular organisms and NCLDVs. They identified that several of these genes, including those encoding the DNA-dependent RNA polymerase (RNAP II), transcription factor IIb, flap endonuclease, and the processing factor proliferating cell nuclear antigen, support the monophyly of the NCLDVs, their ancient origin, and the existence of four domains of life, with the NCLDVs composing the fourth domain.¹⁴ These findings were criticized, based on the assumption that long-branch attraction and compositional heterogeneity might jeopardize the topology of phylogenetic trees.¹⁴⁰ Nonetheless, several other arguments suggest that mimiviruses, marseilleviruses, and other NCLDVs have an ancient origin dating back to the proto-eukaryotes and compose a fourth domain of life.^{14,42} For instance, Suhre¹²⁶ found that the proportion of duplicated genes in Mimivirus is similar to that observed in *Eukarya*, *Bacteria*, and *Archaea*, which is compatible with the deep rooting of this giant virus on the tree of life. In 2009, Yutin et al.¹⁴⁸ updated the core NCLDV gene set on the basis of constructing COGs with an extended number of NCLDV genomes, including those of the Mamavirus and the Marseillevirus. They identified 1,445 NCLDV COGs, so-called NCVOGs, including 177 represented in more than one NCLDV family and five including proteins from all 45 analyzed viruses. Yutin et al. were able to delineate, by means of maximum-likelihood reconstruction, a set of 47 conserved genes that were likely harbored by the genome of the NCLDV common ancestor and proposed that this ancestor may have been a giant virus itself.¹⁴⁸ Additionally, it was highlighted that NCLDVs infect various hosts that belong to the three canonical domains of life, and cross-mapping of the NCLDV and host eukaryotic trees demonstrated that some members of a same NCLDV branch are related to eukaryotic organisms belonging to different supergroups.⁶⁹ These findings suggest that the ancestral NCLDV was involved in early events of eukaryotic evolution, and the hypothesis of a "Big Bang-like" event for the origin of the NCLDVs was proposed by Yutin et al.¹⁴⁸ Moreover, by searching metagenomic data to identify novel deep branches on the tree of life, Wu et al.¹⁴³ found several such branches in the *recA* and *rpoB* gene families, two marker genes widely used for phylogeny reconstructions, and concluded that some may correspond to uncharacterized viruses. Alternatively, they may represent assembly artifacts, recombinants, or paralogs, but these hypotheses are considered unlikely. Importantly, Boyer et al.¹⁴ provided an additional argument in favor of the existence of a fourth domain of life composed of the NCLDVs. Indeed, in addition to phylogenetic reconstructions based on putative orthologous sets of some of the informational genes, they performed hierarchical clustering that relied on the presence/absence patterns in each of the genomes of NCLDVs, *Eukarya*, *Archaea*, and *Bacteria* of the genes assigned to COGs involved in information storage and processing. The topology of the dendrogram tree for this gene content conspicuously showed that a clade composed of the NCLDVs was distinct from three other clades corresponding to *Eukarya*, *Bacteria*, and *Archaea*, the organization of these three latter clades being

congruent with that of the ribosomal phylogenetic trees. Taken together, the aforementioned data support the hypothesis that the mimiviruses, the marseilleviruses, and other NCLDV share a common origin and emerged as deep roots from the rhizome of life, carrying a core genome as ancient as those of *Eukarya*, *Bacteria*, and *Archaea*.^{14,111}

CONCLUSION

Mimivirus and other giant viruses recovered from phagocytic protists considerably broadened the diversity within the viral world and changed our vision of viruses. Future studies should be valuable to gain increased understanding of the epidemiology of these giant viruses in the environment and in clinics, as well as to more accurately define their history and role in the evolution of life.

HISTORY AND IMPORTANCE OF PLANT VIROLOGY

There are far more plant viruses known than all vertebrate viruses combined.¹⁶⁷ This is not surprising given the vastly greater number of plant species than vertebrate species. Instead of attempting to cover all plant viruses in the limited space of this chapter, we provide examples of special importance to the whole field of virology, highlight the relevance to biomedical virology, and discuss features that are unique to plant viruses. For complete descriptions of all plant viruses we refer the reader to the International Committee on Taxonomy Viruses report on virus taxonomy¹⁶⁷ or the ICTV web page (www.ictvonline.org). For a comprehensive textbook on the entire field of plant virology we recommend *Matthews' Plant Virology*.¹⁴¹

History of Plant Viruses as Models for Understanding All Viruses

In the history of virology, investigations of plant viruses have a long and distinguished legacy in telling us what viruses are and how they work (Table 72.1). Many fundamental discoveries on the nature of viruses were made first in studies of Tobacco mosaic virus (TMV).²⁹² The first descriptions of a virus as an infectious agent ("*contagium vivum fluidum*") capable of passing through a porcelain filter that blocked all bacteria, were of TMV^{21,144} (Fig. 72.1). Although some virologists credit Dmitri Ivanovsky with the first discovery of TMV as a filterable agent in 1892,^{200,310} he did not specify or claim that the agent was distinct from other infectious agents such as bacteria. Therefore, many virologists credit Martinus Beijerinck, who performed a series of conclusive experiments in 1898 showing transmission

properties of the filterable agent that caused tobacco mosaic disease,²¹ as the first to discover and conclude that a virus is a new type of infectious agent.^{31,372} This discovery barely preceded the description of foot and mouth disease virus, which was also described in 1898.¹⁹³

The first discoveries of the chemical nature of viruses also resulted from studies of TMV. In 1935, W.M. Stanley found that TMV was (mostly) crystalline protein.³⁰⁹ Initially he detected no carbohydrate or phosphorus and ruled out a nucleic acid component. (TMV particles are 95% protein by mass.) In 1936, F.C. Bawden, N.W. Pirie, J.D. Bernal, and I. Fankuchen detected the carbohydrate and phosphorus and considered the possibility of RNA as a key component of the virion.²⁰ They correctly determined that the agent consisted of long, narrow particles or fibers owing to physical properties of the virus in solution. One demonstration of the anisotropy of the TMV solution was birefringence visible upon gentle agitation by a goldfish swimming in a dilute solution of sap from infected plants (Fig. 72.2A).²⁰ Stanley was awarded the Nobel Prize in Chemistry in 1946 for "purification of enzymes and virus proteins in a pure form." Subsequently, TMV was the first virus on which x-ray crystallography²³ and electron microscopy¹⁶¹ were performed, revealing the infectious agent to consist of surprisingly discrete, symmetrical, highly structured, rod-shaped particles (Fig. 72.2B) (reviewed in [292]). In 1955, Heinz Frankel-Conrat showed, astonishingly at the time, that merely by mixing TMV coat protein subunits and RNA, an intact virion could self-assemble⁹⁷ (Fig. 72.3A). More recently, the first transgenic resistance to a eukaryotic virus was pathogen-derived resistance to TMV, in which expression of the coat protein dramatically delayed and reduced infection by TMV.²⁴⁷

Other plant viruses also played leading roles in virology. In the late 1970s, the first atomic resolution crystal structures of icosahedral virions were solved for Tomato bushy stunt virus (TBSV) and Southern bean mosaic virus (SBMV)^{1,132} (Fig. 72.3B). This proved to be broadly relevant, as the same basic structural rules apply to icosahedral viruses of plants and animals.¹³¹ The first template-specific cell-free replication extracts for positive strand eukaryotic RNA viruses were obtained from Brome mosaic virus (BMV)-infected plants,¹³⁰ enabling dissection of the structure of the origin of replication of a positive-strand RNA virus.⁸¹ In addition, infectious transcripts from a cloned viral genome of a eukaryotic positive-sense RNA virus were obtained for BMV⁴ before any animal virus. Small self-cleaving ribozymes were first discovered in plant viral satellite RNAs,^{95,96,249} paving the way for investigation of hepatitis delta virus RNA, which replicates as a rolling circle with self-cleaving ribozymes like plant satellite RNAs (See Chapter 69), and for construction of site-specific messenger

TABLE 72.1 Major Discoveries Made in Plant Virology Before Similar Discoveries or Methods Were Made in, or Applied to, Mammalian Virology or Biomedicine^a

First discovery	Virus	Year	Reference
Virus is filterable agent	TMV	1892	144
Virus is novel filterable agent and not bacteria	TMV	1898	21
Chemical nature of a virus: crystalline “protein”	TMV	1935	309
Virus is protein with small amount of carbohydrate and phosphorus	TMV	1936	20

AMSTERDAM.

Royal Academy of Sciences, November 26.—Prof. Van de Sande Bakhuyzen in the chair.—Prof. Beijerinck, on a contagium vivum fluidum, causing the spot-disease of tobacco leaves. This disease, also known as the mosaic disease of tobacco leaves, may be inoculated into healthy plants by injecting into the stem, near a bud, sap pressed from infected plants. The active virus passes completely through the pores of very dense porcelain, and can even penetrate into agar by diffusion; therefore it cannot be a contagium fixum in the usual sense, but it must be fluid. Out of the tobacco plant it cannot be made to multiply; but in the dividing tissues of the leaf-rudiments and the meristems of the buds it multiplies freely and over a great extent. A very small drop of the porcelain filtrate can render all the leaves of the infected plant entirely covered with spots, and the sap of these leaves would be sufficient for the contagion of an unlimited number of healthy plants. The virus is destroyed by boiling at so low a degree as 90° C.—Prof.

RNA (mRNA)–cleaving ribozymes,¹³⁴ useful tools for knocking out specific genes.

Studying virus replication in yeast to identify the roles of nearly all host proteins in a high throughput manner has been used to great advantage for the study of plant viruses.^{171,237} In the late 1990s and early 2000s, the existence of RNA-mediated silencing⁸⁷ in innate immunity and the roles of small RNAs in the RNA interference (RNAi) process,¹²⁹ as well as the occurrence of numerous viral suppressors of RNAi (VSRs),^{159,344} were pioneered in studies of plant viruses. Because discoveries in plant virus molecular mechanisms often precede those in animal and human viruses, it is the astute virologist who pays at least passing attention to the plant virus literature.

A reason for the above pioneering discoveries, despite the relatively few resources devoted to plant virus research relative to human virus research, may be that plant viruses are usually easier to work with than vertebrate viruses. They often accumulate to levels in the host that are orders of magnitude greater than those of animal viruses. Many plant viruses are very easy to transmit: simply grinding leaves and rubbing the sap onto other plants usually suffices for efficient inoculation. Local lesion assays on leaves of certain hosts serve as the equivalent of plaque assays in mammalian cell culture. Plants are much less expensive to grow than animals, and regulatory hurdles are fewer because no plant viruses infect mammals. Therefore, in addition to plant pathologists seeking to control disease, researchers who simply want to understand what a virus is and how it works, have been drawn to plant virology.

Economic Importance of Plant Viruses

In addition to the value of plant viruses as model systems, of course many plant viruses have a significant effect on human welfare by reducing crop yield. Recently a list of the “top ten” plant viruses that are either models (but not necessarily major pathogens) or are pathogens of economic impact was compiled.²⁹¹ In Table 72.2, we present a longer list of viruses of significant economic impact. However, it too is incomplete, as many viruses have high impact only in localized areas or occur only sporadically, but cause severe devastation when they strike.

A widespread virus of major economic impact is Tomato spotted wilt virus (TSWV). It infects more than 1,200 plant species and has caused major epidemics in all continents in tomato, pepper, tobacco, peanut, lettuce, potato, and many ornamental species.²³⁸ (Plant viruses are named for the first plant species in which they were discovered, and for the symptoms induced in that particular host–virus interaction. Most plant viruses infect many host species, and symptoms can vary depending on the strain of virus, genotype of host plant, or environment in which the plant is grown.) Cucumber mosaic virus (CMV) infects more than 1,000 plant species.²²⁶ In the presence of a satellite RNA, CMV devastated tomato crops in Europe.¹⁵⁷ Barley yellow dwarf virus and its cousin Cereal yellow dwarf virus are the most economically important viruses of wheat, barley, and oats, especially in Asia, North Africa, South America, and Australia.¹⁸⁸ Potato virus Y (PVY), the type member of the largest plant virus family, the *Potyviridae*, is a major problem in potato. Recently the N strain of PVY has been of particular concern in North America. Citrus tristeza virus led to the loss of more than 100 million trees on the widely used sour orange rootstock worldwide.²²⁵ Loss of sour orange rootstock was a major problem owing to its desirable agronomic qualities. Geminiviruses, which have twin icosahedral particles, unlike any animal virus, devastate dozens of crops and fruits in the tropics. In India viruses in the *Begomovirus* genus of the *Geminiviridae* threaten the livelihoods of small farmers. African cassava mosaic virus, another begomovirus; Groundnut rosette disease, resulting from co-infection of Groundnut rosette virus and Groundnut rosette assistant virus, and a satellite RNA³¹⁸; Rice yellow mottle virus¹⁶⁹; and Sweet potato feathery mottle virus all have caused crop failure and contributed directly to hunger and poverty in subsistence farms in Africa. Then there are viroids, small circular noncoding RNAs unlike any infectious agent known outside of the plant kingdom. The cadang-cadang viroid destroyed more than 30 million coconut palm trees in the Philippines in the 1980s.²⁶⁴ This is just a smattering of examples of economic impact of plant viruses. Economic importance of other viruses is discussed throughout this chapter. Finally, it is important to bear in mind that many viral infections go undiagnosed, dragging down yield without causing obvious symptoms.

TABLE 72.2 Some Economically Important Plant Viruses and Viroids^a

Virus	Economic hosts	Geographic location
African cassava mosaic virus	Cassava	Sub-Saharan Africa
Barley yellow dwarf and cereal yellow dwarf viruses	Wheat, barley, oat, rye, maize, rice	Worldwide
Beet necrotic yellow vein virus	Sugar beet	Europe, North America
Cacao swollen shoot virus	Cacao	West Africa
Cadang-cadang viroid	Coconut palm	Philippines
Citrus tristeza virus	Citrus, esp. sour orange rootstock	Americas, Mediterranean, Australia
Cotton leaf curl virus	Cotton, tomato, chili, beans, sunflower, sesame, soybean, cowpeas, eggplant, sun kukra, and citrus species	Africa, Nigeria, Sudan, Tanzania, Philippines and Pakistan.
Cucumber mosaic virus	>1000 host species, especially, tomato, banana, pepper, cucurbits, legumes	Worldwide
East African cassava mosaic virus	Cassava	Sub-Saharan Africa
Groundnut rosette + Ground nut rosette assistor virus + satellite RNA co-infection	Groundnut (peanut)	Sub-Saharan Africa
Lettuce mosaic virus	Lettuce, other Asteraceae	Worldwide
Papaya ringspot virus	Papaya	Hawaii, SE Asia
Pepino mosaic virus	Tomato	Worldwide
Plum pox virus	Stone fruits	Worldwide
Potato leafroll virus	Potato, tobacco, tomato	Worldwide
Potato spindle tuber viroid	Potato	Worldwide
Potato virus Y	Potato, tomato, pepper, tobacco	Worldwide
Prunus necrotic ring spot virus	Stone fruits	Worldwide
Rice yellow mottle virus	Rice	Sub-Saharan Africa
Rice tungro bacilliform + rice tungro spherical virus co-infection	Rice	Asia
Soybean mosaic potyvirus	Soybean	Worldwide
Sweet potato feathery mottle virus + sweet potato chlorotic stunt virus co-infection	Sweet potato	East Africa, Peru, Israel, USA
Tobacco mosaic virus	Tobacco, greenhouse tomatoes and hundreds of other vegetables	Worldwide
Tomato spotted wilt virus	>1000 host species, especially tomato, peanut, pepper, pineapple and tobacco	Worldwide in temperate regions
Turnip mosaic virus	Oilseed rape, other brassicas, lettuce, pea	Worldwide
Zucchini yellow mosaic virus	Squashes	Worldwide

Beneficial Applications of Plant Viruses

Plant viruses, or sequences from them, have been used, and are being modified and exploited for beneficial purposes. Some viruses confer desirable ornamental symptoms. In 17th century Holland, the delicate striping in flowers caused by Tulip breaking virus led to huge demand for virus-infected tulips in a social phenomenon deemed “tulipmania” (Fig. 72.4). Vast sums greater than the annual salary of most wealthy merchants were promised for individual virus-infected tulip bulbs, until the tulip economic “bubble” burst, leading to a historic price collapse in 1636.¹¹⁸

In modern times, plant viruses are used as expression vectors to produce massive amounts of protein in plant cells, often for human or veterinary pharmaceutical purposes.²⁰³ Gene expression control sequences, such as the 35S RNA promoter from Cauliflower mosaic virus,^{162,233} and the omega translation enhancer sequence from TMV,¹⁰⁵ are used widely in genetically engineered plants. In the last decade, the development of many plant viruses as virus-induced gene silencing (VIGS) vectors

has revolutionized plant genetics by providing a quantum leap in the speed with which geneticists can knock down expression of, and thus determine function of, any plant gene of interest, including essential genes that would be lethal if knocked out by other means.^{18,45,79,375} Plant viral suppressors of silencing are used to boost expression of transgenes in plants.³⁴⁵ Plant virus particles engineered to display epitopes from animal or human pathogens show great potential for improved, inexpensive vaccines.^{222,311} Plant virus particles also are being modified and exploited to function as drug delivery vehicles,¹⁷⁰ tiny vesicles for nanomedicine,²⁰⁴ and as components of rechargeable batteries.⁵³

How Plant Viruses Differ from Animal Viruses

Obviously plant viruses undergo the same basic processes of entry, disassembly, gene expression, replication, and encapsidation as animal viruses. However, the nature of the host has led to some important differences. Unlike animal cells, each plant cell is surrounded by a dense cell wall consisting of

FIGURE 72.4. Tulips infected with Tulip breaking virus, a desirable infection in 17th century Holland. (Copyright Fitzwilliam Museum, University of Cambridge.)

cellulose, pectins, lignins, and other material impenetrable to a virion. However, plant cells are connected by small openings called plasmodesmata through which small molecules, proteins, and sometimes RNAs pass.^{198,199} Plasmodesmata are roughly analogous to gap junctions in vertebrate cells, but are perhaps more similar to recently discovered tunneling nanotubes in animal cells.¹⁰³ To infect the whole plant, plant viruses encode one or more movement proteins (MPs) that facilitate cell-to-cell movement of viral RNA or whole virions through the plasmodesmata. Plants lack an open vascular system. Sugars, hormones, and certain proteins and RNAs are transported through the phloem. Unlike the open tubes formed by blood vessels, the phloem transport system consists of cells connected via sieve elements. For viruses to travel “long distance” (from leaf to leaf) they have adapted ways to move from one phloem cell to the next through the sieve elements.⁸⁹

Plants have a much more developed RNA-based innate immune system than mammals, which rely on other innate defenses, such as protein kinase RNA-activated (PKR) or retinoic acid-inducible protein I (RIG-I) that are absent or reduced in plants. Hence all plant viruses appear to encode viral suppressors of RNAi (VSRs), proteins that inhibit the RNA-based gene silencing system in plants⁷¹ (see section Host Defenses

and Viral Countermeasures). Plants are sessile, so they rely more on insect vectors for plant-to-plant transmission. Therefore, most plant viruses are “arboviruses” (see section Vector Transmission of Plant Viruses).

Plant viruses are smaller and simpler than most animal viruses (Fig. 72.5). The largest plant virus genome is about 20 kb, but most plant virus genomes are 10 kb or smaller. The small size may be required for cell-to-cell movement through the plasmodesmata. Many plant viruses form flexuous rod-shaped virions that are rare among animal viruses, or rigid rods, such as TMV, a morphology not known among animal viruses. There are no plant viruses with large DNA genomes (>10 kb) or with linear DNA genomes. Plant retroviruses are not known to exist, but plant pararetroviruses and plant retrotransposons are well characterized. No plant viruses are known to integrate their genome into the host genome as part of the replication cycle, but an infectious copy of banana streak pararetrovirus has integrated into the banana genome.¹¹⁰ Although normally silenced, the expression of the integrated viral genome can be activated by vegetative propagation methods, creating infections that have become a major problem in banana breeding programs.⁶³

Many plant viruses have multipartite, positive-sense RNA genomes, which are absent among mammalian viruses. Interestingly, many insect viruses resemble plant viruses in this way. A few plant viruses may have escaped from (or co-evolved with) the mammalian virus world, as some are in the same family or order as mammalian viruses. These include members of the *Bunyaviridae* (e.g., TSWV), *Rhabdoviridae* (e.g., Lettuce infectious yellows virus), *Reoviridae* (e.g., Fiji disease virus of sugarcane), and *Picornavirales* (e.g., Cowpea mosaic virus).¹⁷⁶ They represent a minority of all plant viruses, and the plant rhabdoviruses and bunyaviruses are the only enveloped plant viruses. Because of the similarities of these viruses to animal viruses that are discussed elsewhere in this volume, this chapter focuses primarily on the plant viruses that do not fall into the same families as animal viruses.

BROMOVIRIDAE FAMILY AND TOBAMOVIRUS AND TYMOVIRUS GENERA

The *Bromoviridae* family includes one of the best-characterized RNA viruses of eukaryotes, BMV (genus *Bromovirus*), as well as some of the most widespread and economically important plant viruses, such as Cucumber mosaic virus (CMV, genus *Cucumovirus*) and Alfalfa mosaic virus (AIMV, genus *Ilarvirus*). TMV, for which genus *Tobamovirus* is named, is an extremely efficiently transmitted pathogen of tobacco and tomato, and thus is often a problem, especially in greenhouses.

Unlike positive-sense RNA viruses of vertebrates, viruses in the *Bromoviridae* and many other positive-sense plant viruses have multipartite genomes (Fig. 72.6). The genome of *Bromoviridae* consists of three RNAs, each of which is packaged in a separate icosahedral virion. A fourth, subgenomic RNA (sgRNA), representing the 3' end of RNA 3, is co-encapsidated with RNA 3. An exception in particle structure is genus *Ilarvirus*, in which the virion is bacilliform and the length is proportional to the length of the encapsidated RNA.²⁷ With the possible exception of ilarviruses (including AIMV) all of the RNAs of the *Bromoviridae* feature a transfer RNA (tRNA)-like structure (TLS) at the 3' end. These are discussed in detail later in this section.

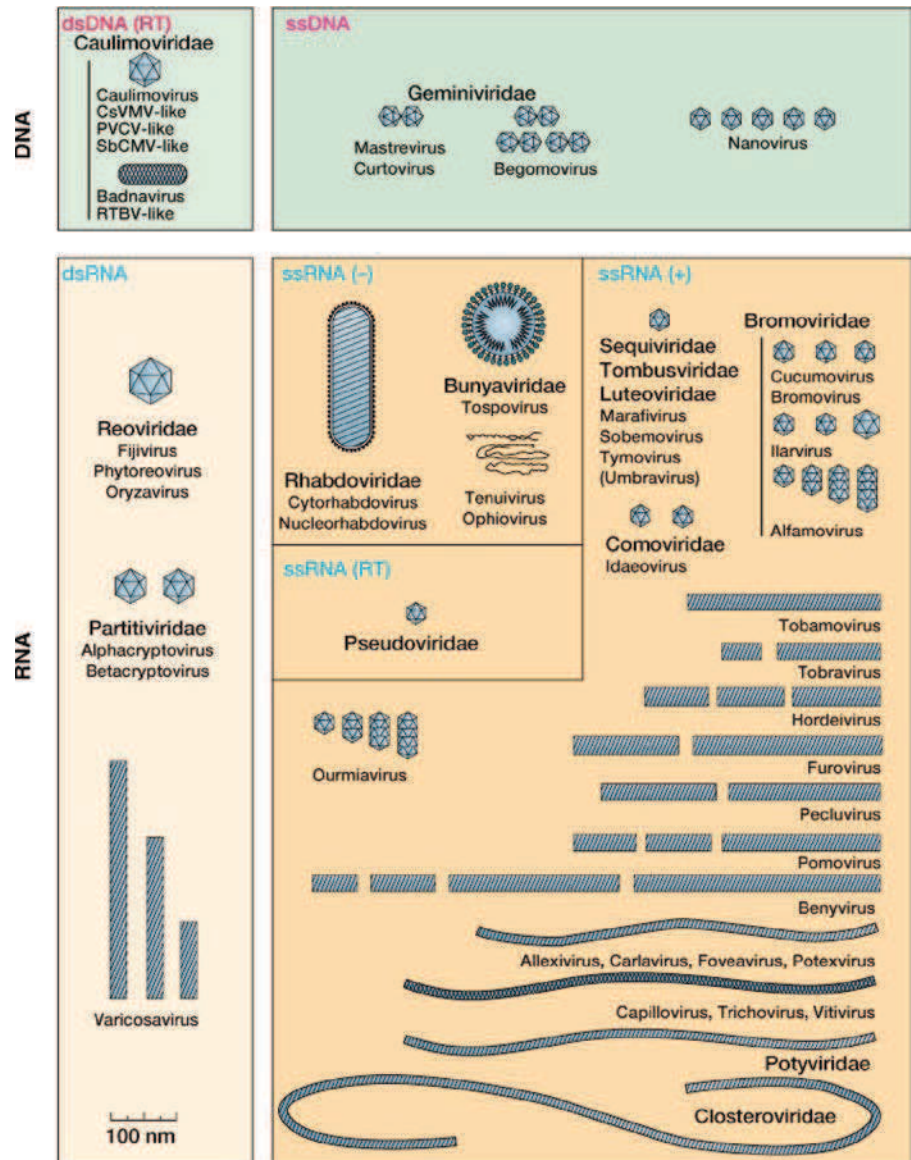

FIGURE 72.5. Plant viruses arranged by virion structure. (From King AMQ, Adams MJ, Carstens EB, Lefkowitz EJ. *Virus Taxonomy: Ninth Report of the International Committee on Taxonomy of Viruses*. Philadelphia: Elsevier; 2012.)

In the *Bromoviridae*, RNAs 1 and 2 are each about 3-kb long.²⁷⁸ RNA 1 encodes an open reading frame (ORF) that includes a methyl transferase domain for capping viral RNAs and an RNA helicase domain. The virus encodes its own capping enzyme because the entire replication cycle takes place outside of the nucleus where capping of host mRNA occurs. The ORF that occupies most of RNA 2 encodes the viral RNA-dependent RNA polymerase (RdRp). A small ORF (2b) that overlaps with the 3' end of ORF 2 in the cucumo and ilarviruses encodes a viral suppressor of RNA-mediated silencing (VSR), a key innate immune response in plants³⁷ (discussed in the Host Responses section of this chapter).

The coding region of the ~1.7-kb RNA 3 is split into two nonoverlapping ORFs (Fig. 72.6). ORF 3 in the 5' end encodes the cell-to-cell movement protein. The 3' end of RNA 3 encodes the coat protein (CP) in ORF 4. ORF 4 is translated from RNA 4, an sgRNA derived from the 3' end of RNA 3. It is 3'-co-terminal with RNA 3, but is truncated so that the 5' end of

RNA 4 is just upstream of the CP ORF start codon. This permits highly efficient translation of CP from monocistronic RNA 4 by conventional ribosomal scanning from the 5' end of the RNA.

Genus *Tobamovirus* is in the *Virgaviridae* family, which is similar to the *Bromoviridae* in (a) the sequences of the replication genes,¹³⁵ (b) expression mechanisms of 3'-proximal ORFs via 3'-co-terminal sgRNAs, and (c) presence of a tRNA-like structure at the 3' end of the genome (Fig. 72.7). Tobamoviruses differ from *Bromoviridae* in that (a) they have a monopartite genome, (b) the polymerase ORF is expressed via translational readthrough of the stop codon of the upstream ORF that encodes the methyl transferase and helicase functions, (c) the movement protein is translated from a subgenomic mRNA, (d) sgRNAs are not encapsidated, and (e) the virions are helical rods. Genomes of viruses in genus *Alphavirus* of the *Togaviridae* resemble tobamoviruses as well.⁵ The replication genes have significant sequence homology, the RdRp is expressed via in-frame readthrough, and the structural proteins are translated via 3'-co-terminal subgenomic

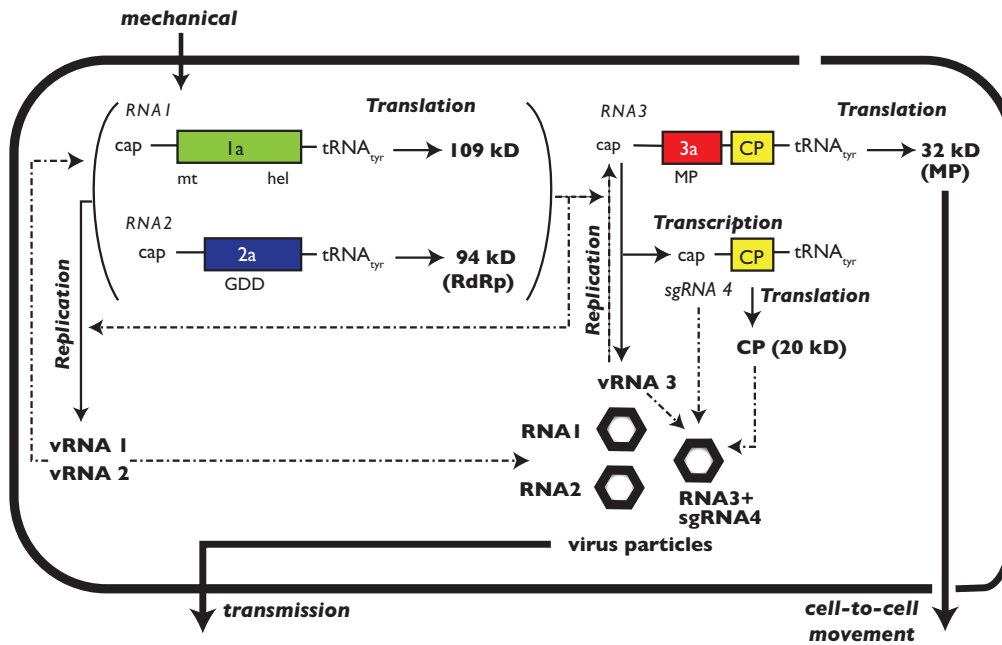

FIGURE 72.6. Replication strategy of Brome mosaic virus. (Modified from: Lazarowitz S. Plant Viruses. In: Knipe DM, Howley PM, eds. *Fields Virology* 5th ed. 2000).

RNA (Fig. 72.8). However, alphaviral RNAs lack 3' TLSs, and the genomes and virions are more complex than those of plant viruses.

Tymoviruses (*Tymoviridae*) are not closely related to the tobamo and bromoviruses, but they share the presence of a TLS

at the 3' end. The movement protein is encoded in an ORF that overlaps a long section of the RdRp ORF at the 5' end of the genome (Fig. 72.9). Like the bromoviruses and tobamoviruses, and many other plant viruses, the CP is translated from a 3'-co-terminal sgRNA.

FIGURE 72.7. Replication strategy of Tobacco mosaic virus. (Modified from: Lazarowitz S. Plant Viruses. In: Knipe DM, Howley PM, eds. *Fields Virology* 5th ed. 2000).

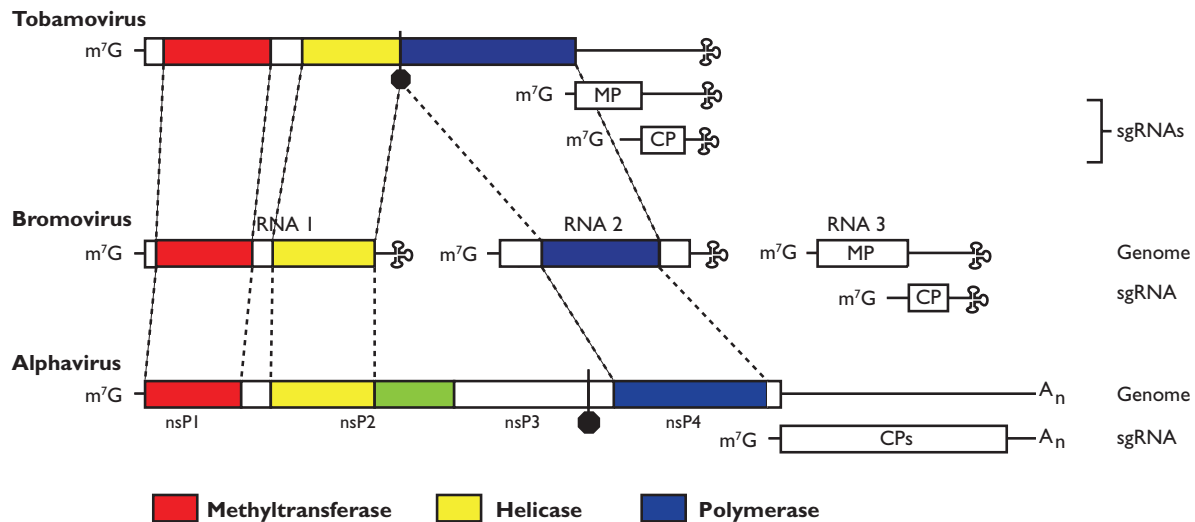

FIGURE 72.8. Relationships between Bromoviridae, Tobamoviruses, and Alphaviruses.⁵

Genome Replication

The TLS at the 3' end of the genome of the above viruses is the origin of replication for negative-strand RNA synthesis.^{81,211} Although the viral RdRp catalyzes RNA synthesis directed by the viral template, like all RNA viruses, the full viral replicase holoenzyme requires host-encoded proteins to carry out the regulated processes of template recognition and synthesis of appropriate ratios of negative and positive-strand RNA.²⁵⁵ Because positive-strand is perhaps hundreds-fold more abundant than negative strand, the availability of each strand as template is highly regulated, both by alternative structures in the RNA and its recognition by host proteins.^{234,243}

The TLS resembles tRNA in the three-dimensional structure, and often has additional non-tRNA-like features such as extra helices. The actual base pairing to form the tRNA shape

is different from that of normal tRNA, because the acceptor stem consists of two stacked helices formed by a pseudoknot (Fig. 72.10). Different domains have been identified that confer specific recognition of the RNA by the replicase.⁸² In BMV, these include the “anti-codon loop” and parts of the acceptor stem. Different regions are required for recognition by the tRNA aminoacyl synthetase that tyrosylates the BMV TLS.⁸³

The small size of the BMV genome and the pioneering work of the Paul Ahlquist’s lab have made BMV one of the best characterized models for understanding mechanisms and host components involved in replication of any eukaryotic virus. By generating a BMV RNA replication system in yeast, Ahlquist and colleagues stably transformed yeast with BMV RNAs 1 and 2, the products of which were capable of replicating RNA 3 in yeast. They then screened for mutants of these yeast lines

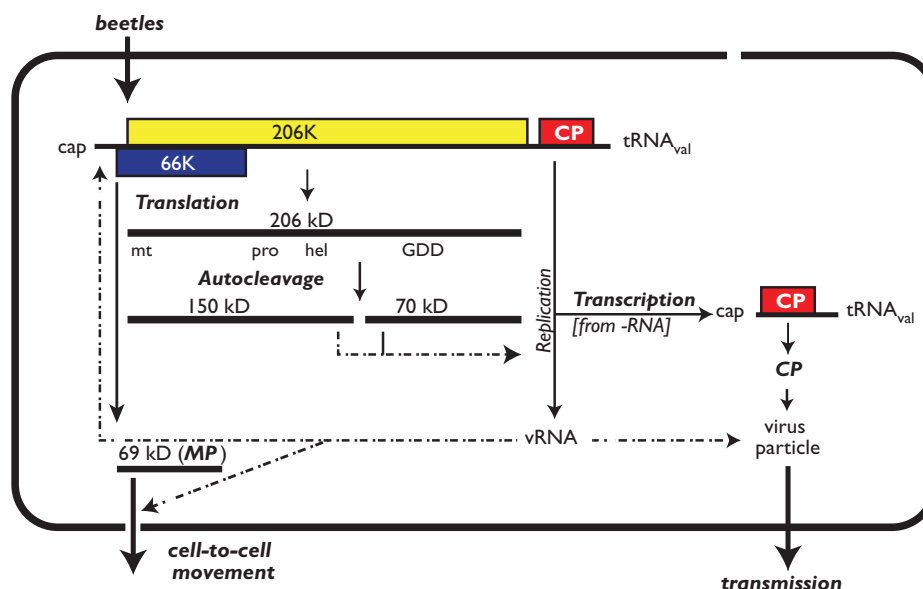

FIGURE 72.9. Replication strategy of Turnip yellow mosaic virus. (Modified from: Lazarowitz S. Plant Viruses. In: Knipe DM, Howley PM, eds. *Fields Virology* 5th ed. 2000).

FIGURE 72.10. Transfer RNA (tRNA)-like structures.⁸⁰ Numbering is from the 3' end of the genome. Arrows indicate phosphodiester bonds distorted to allow depiction of structure in two dimensions. UPSK, upstream pseudoknot.

that could not support viral RNA synthesis but which were otherwise normal.¹⁴³ This revealed many new and sometimes surprising host factors required for RNA virus replication.

Host proteins involved in the BMV replicase include a subunit of translation initiation factor eIF3,²⁵⁵ and the Lsm1-7 complex.⁷⁴ The Lsm1-7 complex normally regulates mRNA decay. In BMV RNAs it binds the TLS and A-rich internal sequences and regulates both replication and translation, leading to the proposal that it regulates the switch between translation and replication,¹⁰² processes that are incompatible on the same RNA template.¹⁰⁷ This is also facilitated by the BMV 1a protein that binds the replication element (RE) stem-loop in each viral RNA, bringing the RNA into replication vesicles.²³²

Using electron microscopy and tomography, Ahlquist and colleagues showed that BMV replicates on perinuclear endoplasmic reticulum (ER) membranes.²⁷¹ Invaginations form vesicles that serve as replication factories (Fig. 72.11). Each vesicle is formed by, and lined with, hundreds of copies of the multifunctional 1a protein, and contains 10 to 20 copies of the RdRp (2a protein) and just a few copies of positive- and negative-strand RNA.²⁹⁴ The hypothesized mechanism is that the RdRp copies

FIGURE 72.11. Model for assembly and function of the Brome mosaic virus (BMV) RNA replication complex. BMV1a accumulates on perinuclear endoplasmic reticulum (ER) membranes, recruits 2a^{pol}, binds the replication element (RE) in genomic RNA (red), and incorporates both into the interior of a spherule. This serves as an isolated compartment free of ribosomes or RNA-based antiviral systems. Newly synthesized RNAs are ejected through the neck-like opening in the ER. (Reprinted with permission from den Boon JA, Ahlquist P. Organelle-like membrane compartmentalization of positive-strand RNA virus replication factories. *Ann Rev Microbiology*. 2010;64:241–256.)

viral RNA, ejecting the positive strand out through the neck of the vesicle as the RNA is synthesized. The vesicle keeps the RNA (in particular the double-stranded replicative intermediate) sequestered from antiviral defenses, such as virus-induced RNA silencing induced by double-stranded RNA (dsRNA), and also from the ribosomes, which would block replication by translating the positive strand. The positive strands ejected from the vesicles would be available for (a) translation of more viral proteins, (b) serving as template for additional replication in another vesicle, (c) transport to neighboring cells, or (d) encapsidation. This general strategy of RNA synthesis in a membranous vesicle lined with a viral RNA binding, helicase-like protein, and containing low numbers of RdRp and template RNA may apply to all viruses in the alphavirus-like superfamily of viruses.^{3,70} This underscores the value of a plant virus as a model for understanding mechanisms of human virus replication.

tRNA-like Structures

TLSs are widespread among plant viruses, but apparently absent in animal viruses. In addition to the *Bromoviridae*, plant viruses in the *Tobamovirus* (e.g., TMV), *Tymovirus* (e.g., Turnip yellow mosaic virus, TYMV), and four other genera also have a TLS at the 3' end of the genome; see reference 80 for an excellent review. All TLSs differ from tRNA by having a pseudoknotted acceptor stem (see Fig. 72.10) instead of a simple helix. The TYMV TLS is the simplest and most tRNA-like of the TLSs, whereas the BMV TLS is the most complex, containing extra stem-loops unlike anything in tRNA. The TLS plays a plethora of roles in virus infection, which vary between viruses. Three biochemical properties that TLSs share with tRNAs are: (a) they can be aminoacylated with a specific amino acid, (b) the aminoacylated form binds translation elongation factor eEF1A•GTP complex, and (c) they serve as a substrate for CTP:ATP:tRNA nucleotidyltransferase (CCA-adding enzyme), which adds the 3'-terminal CCA sequence to tRNAs.⁸⁰

The role of aminoacylation is not to donate the amino acid to a growing polypeptide as in normal translation. For TYMV, it was reported, using only cell-free extracts, that the valine with which the TLS is acylated is donated as the first amino acid in a novel translation initiation mechanism.¹⁶ However, this was shown not to be the case *in vitro* or in plant cells for TYMV²⁰⁵ or for other TLS-containing viruses.^{17,280} Aminoacylation does enhance translation.^{104,206} It may functionally replace the role of the poly(A) tail in stimulating translation initiation. In the case of TMV, a pseudoknot repeat domain upstream of the TLS (see Fig. 72.10) plays this role,¹⁰⁶ and aminoacylation is not required.

Owing to its presence at the 3' end, the TLS is also the origin of minus-strand synthesis.⁵⁰ RNA synthesis begins by incorporation of a guanosine monophosphate complementary to the penultimate base of the genome, that is, the middle base of the CCA at the 3' end.^{211,304} For BMV and TYMV, it has been shown that the sequences and structures within the TLS recognized and required by the replicase differ from those required for aminoacylation (and hence eEF1A binding).^{42,67,83} Binding of eEF1A to the aminoacylated RNA inhibits minus-strand synthesis, possibly by blocking the replicase from interacting with the CCA terminus. This may shut off minus-strand synthesis to favor plus-strand synthesis, which initiates at the 3' end of the minus strand that has no TLS. This would favor generation of the high ratio of (+) to (−) strand RNA in these positive-strand RNA viruses. It may also allow the viral RNA to be translated

but not replicated, two functions that are presumed to be incompatible on the same RNA molecule. However, a mechanism must also exist to allow replicase to outcompete eEF1A and the tRNA synthetase for access to the 3' end.

One tRNA mimicry function that has an obvious role in RNA replication is substrate for the CCA-adding enzyme. Because minus-strand synthesis initiates at the penultimate base, the terminal A must be added in a nontemplated fashion. The CCA-adding enzyme provides this function because it requires no template to add the CCA to the 3' end of tRNA. Mutations that prevent CCA addition block replication, demonstrating that the CCA-adding enzyme serves as a telomerase and the CCA is the telomere.²⁶⁵ This function extends to the tobamoviruses, which lack a TLS but have a tRNA-acceptor arm mimic, which allows it to be a substrate for CCA addition.³³²

Finally, the TLS is required for encapsidation of BMV RNAs,⁵⁶ but not all other TLS-containing viruses.^{9,54} The role of the TLS in packaging viral genomes can be difficult to discern due to the co-replicative nature of RNA packaging.^{10,54} In summary, TLSs play multiple roles for each virus, and the roles and requirements often differ between viruses.

TOMBUSVIRIDAE, LUTEOVIRIDAE, SOBEMOVIRUS, AND UMBRAVIRUS GENERA

The *Tombusviridae* family encompasses many viruses in nine genera. These viruses are grouped into the same family by having (a) related RdRp's; (b) an icosahedral, T = 3 virion; (c) an uncapped, unmodified, nonpolyadenylated positive-sense genomic RNA; and (d) a 4- to 6-kb genome which, with one exception, is monopartite. The exception is the *Dianthovirus* genus, which has two genomic RNAs. The Tombusvirid genome encodes a highly expressed ORF (ORF 1) fused to the RdRp ORF via readthrough of a leaky stop codon in most cases, or a -1 ribosomal frameshift in the dianthoviruses (Fig. 72.12). Because readthrough and frameshifting are rare events, the ORF 1 product is far more abundant than the RdRp, the amino terminus of which is encoded by ORF 1. These are the only proteins needed for RNA replication.³⁵⁸ The downstream genes encode one or more movement proteins, the coat protein, and a suppressor of RNA-mediated silencing (VSR). These ORFs are translated from subgenomic (sg) mRNAs generated during virus infection.¹⁵² Specialized translation events such as ribosome initiation at more than one start codon (via leaky scanning) are necessary for translation of some of these downstream ORFs, depending on the genus. The sgRNAs are not encapsidated, and they are generated during the process of RNA replication.

The function of the protein encoded in ORF 1 is best characterized for TBSV, the type member of the *Tombusvirus* genus. This protein, (33 kD P33 in TBSV), is an RNA-binding protein that binds a specific stem-loop in TBSV RNA.²⁴⁶ About 1% to 5% of these proteins contain the RdRp fused to the C terminus via ribosomal readthrough of the ORF 1 stop codon, making it a 92-kD protein. This is the only way the RdRp is translated. This relationship of a highly abundant RNA-binding protein (RBP), a few copies of which contain the viral RdRp by virtue of the longer C terminus, resembles that of the gag-pol protein of yeast LA virus, most retroviruses, and the protein products of RNAs 1 and 2 of the *Bromoviridae*. In the latter case, rather than a translational recoding event, the

FIGURE 72.13. Model of Tomato bushy stunt virus (TBSV) replication. Host factors shown in green circles and green arrows are required, whereas factors in blue circles and blue arrows inhibit TBSV replication. Hsp70 is colored uniquely due to the essential role of Hsp70 in several steps in TBSV replication. Active and inactive (phosphorylated) viral p33 proteins are shown as black or pink circles, respectively. Active and inactive forms of p92 are shown as green and red circles, respectively. (Reprinted with permission from Nagy PD, Pogany J. Global genomics and proteomics approaches to identify host factors as targets to induce resistance against tomato bushy stunt virus. *Advances in Virus Research* 2010;76:123–177.)

The functional replicase is assembled or activated on the membrane by endosomal sorting complex required for transport (ESCRT) proteins, CDC34 and HSP70. Membranes are altered by sterols, and by forming invaginations and replication vesicles. eEF1A and PMR1, the $\text{Ca}^{2+}/\text{Mn}^{2+}$ pump, facilitate RNA synthesis.¹⁴⁶ Glyceraldehyde 3-phosphate dehydrogenase (GAPDH) favors positive-strand synthesis, possibly by facilitating its release from the replicase complex. Phosphorylation of p33/p92 inhibits their RNA-binding function, leading to disassembly of the replicase complex. Some progeny RNA is degraded by XRN1,²⁹⁶ exonuclease which is not surprising given that the viral RNA has an unmodified 5' end. Apparently secondary structure at the 5' end, or sheer numbers of viral RNAs generated during replication, prevents total degradation of viral RNA by XRN1. Many of the events and host enzymes were shown to apply to mammalian virus replication. Therefore, this extremely tractable yeast-plant system to investigate TBSV replication may have relevance to many stages of human RNA virus replication.

Luteoviridae and Genus Umbravirus

Two virus genera that are not in the *Tombusviridae*, but which have all of the above properties, including polymerase genes and

cis-acting replication and translational control signals highly homologous to those of the *Tombusviridae*, are *Luteovirus* and *Umbravirus* (see Fig. 72.12). Genus *Luteovirus* has been assigned to the *Luteoviridae* family based on the property that its members are transmitted by aphids in a circulative, persistent manner (see vector transmission), unlike any *Tombusvirid*. The coat protein is similar to that of some *Tombusviridae*, except that some (perhaps 5% to 10%) of the CP subunits in the virion contain a ~50-kD C-terminal extension necessary for the unique aphid transmission properties.³⁵ This extension is added by in-frame readthrough of the CP ORF stop codon.³⁹ Luteoviruses (i.e., genus *Luteovirus* members) have all the replication and gene expression features of *Tombusviridae*, and differ only in the CP, movement protein, and possibly silencing suppressor (which is unidentified to date). The genera within *Tombusviridae* vary in these same properties. Thus it has been proposed that genus *Luteovirus* of the *Luteoviridae* could be reassigned to the *Tombusviridae*.²¹⁵

The *Luteoviridae* family comprises three genera: *Luteovirus*, *Polerovirus*, and *Enamovirus*. They include major pathogens such as the Barley yellow dwarf viruses (genus *Luteovirus*) and Cereal yellow dwarf viruses (genus *Polerovirus*) that afflict wheat, barley, and oats wherever these crops are grown; Potato

leafroll polerovirus in potato (worldwide); Beet mild yellowing virus (despite its name, a major problem in European sugar beet); and Pea enation mosaic virus (PEMV, a complex of the sole *Enamovirus* and an *Umbravirus*), which causes major losses periodically in peas and lentils from the Pacific Northwest to the Middle East.⁶⁶

Poleroviruses and the single-member genus *Enamovirus* (Pea enation mosaic virus 1, PEMV1) are distinct from genus *Luteovirus* and the *Tombusviridae*. The RdRp sequence is more closely related to those of viruses in genus *Sobemovirus* (no family assigned) than it is to genus *Luteovirus* or any *Tombusviridae* (see Fig. 72.12). In addition, it contains a genome-linked protein (VPg) attached covalently to the 5' end of its genomic RNA. There are no close similarities in translational control signals to those shared among genus *Luteovirus* and some of the *Tombusviridae*. The only features shared closely among the three *Luteoviridae* genera and which distinguish them from *Tombusviridae* and sobemoviruses are that they are persistently transmitted by aphids, and with the exception of PEMV, they are confined to the phloem and not mechanically transmissible. These properties are conferred by the CP-RTD protein in the virion¹²¹ and probably by the movement protein, which is encoded by an ORF embedded within the CP ORF, in a different reading frame. Unlike the replication genes and *cis*-acting signals, these three genes have higher homology within the *Luteoviridae* than they do with viruses outside the family.²¹⁵ To summarize the relationships, viruses in the genus *Luteovirus* appear to be *Tombusviridae* that acquired a “*Luteoviridae* block” of ORFs: the CP-RTD and overlapping MP ORF. Polero and enamoviruses resemble sobemoviruses that acquired the same *Luteoviridae* block. How the *Luteoviridae* block first evolved is unknown.

Umbraviruses are unusual in that they encode no coat protein. Instead, they rely on co-infection with a specific partner virus in either the *Polerovirus* or *Enamovirus* genus of the *Luteoviridae* family, for encapsidation and transmission to other plants by aphids.³¹⁶ Umbraviruses encode their own polymerase, enabling them to replicate in, and infect, plants on their own. Therefore, they are not satellite viruses. However, satellite RNAs of umbraviruses exist and play a role in disease. Groundnut rosette umbravirus, in combination with a true satellite RNA, and the mild polerovirus, Groundnut rosette assistant virus, together form a tripartite complex that leads to devastating losses of groundnuts (peanuts) in sub-Saharan Africa.^{276,317}

Although they lack a CP and do not form virions on their own, umbraviruses form a ribonucleoprotein (RNP) complex containing the viral genome and the protein encoded by ORF 3. Formation of this structure requires movement of the ORF 3 protein through the Cajal bodies to the nucleolus.¹⁶⁶ There, the ORF 3 protein interacts with fibrillarin, which leads to formation of nuclease-resistant RNPs capable of long-distance movement in the phloem.¹⁶⁵ Although not a virion, the RNase-resistant nature of the RNP suggests it functionally performs some of the role of a virion for movement within, but not between, plants.

Gene Expression

CAP-INDEPENDENT TRANSLATION

The RNAs of most plant viruses lack a 5' cap structure, which is essential for translation of host genes. Instead, uncapped plant viral RNAs contain a cap-independent translation element (CITE). Some of these elements may behave like an animal virus internal ribosome entry site (IRES) upstream of

the initiation codon. However, *Tombusviridae*, luteoviruses, umbraviruses, and *Nepovirinae* contain CITEs in the 3' UTR of their genomes, and, other than in the *Nepovirinae*,¹⁵⁸ the 3' CITEs do not confer internal ribosome entry.²¹⁶ These are unlike any known animal virus translation element.

3' CITEs fall into about seven different classes, based on their sequence and structural features (Fig. 72.14A). These elements appear to stimulate translation by binding a surface of the translation initiation factor complex, eIF4F, with high affinity. eIF4F is a rate-limiting, highly regulated, heterodimeric initiation factor. In plants, it has two subunits, the cap-binding protein, eIF4E, and the multifunctional scaffolding protein, eIF4G. eIF4E normally binds the 5' cap, bringing eIF4G to the mRNA. eIF4G binds numerous other initiation factors that ultimately recruit the 40S ribosomal subunit, and it facilitates scanning of the ribosome to the start codon.¹⁴⁷ The 3' CITE of Barley yellow dwarf virus (BYDV) and related viruses (BYDV-like translation enhancer, BTE) binds eIF4G with high affinity and does not bind or require eIF4E.³²² In contrast, the 3' CITE of Panicum mosaic virus (PTE) and certain other *Tombusviridae* and one umbravirus, has a structure that is completely different from that of BTE, and it binds eIF4E with high affinity.³⁵¹ This was surprising because eIF4E was known to bind only capped RNAs, owing to the requirement for the m⁷GpppN (cap structure) at the 5' end to fit in the cap-binding pocket of eIF4E. The 3' translation enhancer domain (TED) of Satellite tobacco necrosis virus (STNV)¹¹¹ and the I-shaped 3' CITEs of Maize necrotic streak virus (MNeSV) and Melon necrotic spot virus (MNSV)²³⁰ bind eIF4F, but not to either individual subunit with high affinity. Genetic evidence supports an interaction between the I-shaped CITE and eIF4E.³²⁵ The T-shaped structure (TSS) of Turnip crinkle virus (TCV) RNA has been shown to bind directly to the yeast 60S ribosomal subunit.³⁷⁸ All of the above CITEs are in genomes of the *Tombusviridae*, with the exception of those in the related *Luteovirus* and *Umbravirus* genera. Interestingly, the class of 3' CITE associated with a particular virus does not always correlate with the classification of the virus. Finally, the nepoviruses, which are completely unrelated to the *Tombusviridae*, being in the *Picornavirales* order, also have a 3' CITE in their genomes. It differs from the others by acting in conjunction with a 5' UTR to confer IRES function.¹⁵⁸

The location of the CITE in the 3' UTR raises the question of how it facilitates ribosome entry at the 5' end of the genome. In most cases, this is achieved by long-distance base pairing between the 3' CITE, or an adjacent sequence, and the 5' UTR.^{90,124} One model for this mechanism is that the 3' CITE binds eIF4F, and simultaneously base pairs to the 5' UTR, placing eIF4F in the proximity of the 5' terminus to which it recruits the 40S ribosomal subunit (Fig. 72.14B).²⁶³ An alternative possibility is that the factors and ribosomes are all recruited to the 3' CITE, which then delivers the ribosome to the 5' UTR by long-distance base pairing. In TCV RNA, it is proposed that the 60S subunit bound to the TSS interacts with the 40S subunit at the 5' end, thus circularizing the viral mRNA.³¹²

The location of the CITE in the 3' UTR may provide an elegant mechanism to regulate the switch from translation of the first viral RNA molecule that enters the cell to replication (Fig. 72.15). Circularization and translation take place in the absence of viral proteins and would be the first event as the RNA is released from the first invading virion. Once synthesized from the pioneer viral RNA, the RdRp would initiate negative-strand

FIGURE 72.14. Cap-independent translation elements (CITES) in the 3' UTRs of plant viruses. **A:** Secondary structures of elements from representative viruses of each class of element. Required, conserved bases are in *italics*. Bases that base pair to the 5' UTR are in *bold*. (**A** adapted and updated from Miller WA, Wang Z, Treder K. The amazing diversity of cap-independent translation elements in the 3'-untranslated regions of plant viral RNAs. *Biochem Soc Trans* 2007;35:1629–1633.) **B:** Model for cap-independent translation mediated by a 3' CITE. (**B** modified from Treder K, Pettit Kneller EL, Allen EM, et al. The 3' cap-independent translation element of Barley yellow dwarf virus binds eIF4F via the eIF4G subunit to initiate translation. *RNA* 2008;14:134–147.) The 3' CITE binds eIF4F and base pairs to the 5' UTR, placing eIF4F in proximity of the 5' end where eIF4F recruits the 43S ribosomal subunit preinitiation complex, which then scans to the initiation codon (AUG). Alternatively, the 43S subunit may be recruited to the 3' CITE and delivered to the 5' end by base pairing.

FIGURE 72.15. Model for shut-off of translation to permit replication of Barley yellow dwarf virus (BYDV).²¹⁷ **A.** Long-distance base pairing allows for translation initiation (magenta) and frameshifting (yellow). **B.** The RdRp produced by translation (blue sphere) copies viral RNA starting from the 3' end. This disrupts the upstream frameshifting and initiation events, freeing the RNA of ribosomes to permit complete genome replication (**C**). This potential mechanism of initiation shut-off by the RdRp in the 3' UTR applies to all viruses with a 3' CITE. The frameshift shut-off applies to luteoviruses and dianthoviruses, which have a long-distance frameshift element in the 3' UTR.

synthesis at the 3' end of the genome and begin copying in the 5' direction. If it encountered ribosomes still translating the viral RNA, the RdRp would be unable to proceed and replication would be blocked.¹⁰⁷ Instead, upon encountering the CITE in the 3' untranslated region, the RdRp could disrupt this structure, prevent both eIF4F binding and long-distance base pairing, thus shutting off translation initiation at the 5' end, 4 kb upstream, long before the RdRp would encounter a ribosome. This would free the genome from ribosomes and permit full-length negative-strand synthesis. The luteoviruses and dianthoviruses also harbor a sequence in the 3' UTR required for the frameshift event that is located at the start of the RdRp ORF about 3 to 4 kb upstream (see Fig. 72.12). The RdRp could disrupt this interaction as well (Fig. 72.15).

TRANSLATION OF POLYCISTRONIC PARARETROVIRUS mRNAs

Plant pararetroviruses in the *Caulimoviridae* and *Badnaviridae* families express multiple genes from a large polycistronic mRNA by two complicated translation initiation mechanisms: ribosome

shunting and ribosome reinitiation.²⁸² Multiple large ORFs are translated from the 35S pregenomic RNA of CaMV, the best characterized plant pararetrovirus. Translation initiates at the 5' end via a ribosome shunt mechanism.¹⁰⁰ The highly structured 5' leader contains several small ORFs (sORFs). The 40S ribosomal subunit binds in a normal cap-dependent mechanism and scans to the first sORF. The six codon sORF is translated, and termination at the sORF stop codon takes place immediately upstream of a large stem-loop structure. The 40S subunit then jumps across the structured region, skipping several sORFs in the process, and resumes scanning until it reaches the start codon of the first large ORF, ORF VII where translation reinitiates.²⁸¹ After this mechanism was discovered in CaMV, a very similar shunting mechanism was discovered in translation of adenovirus late mRNAs, demonstrating unexpected relevance of this plant virus mechanism to mammalian virology.³⁷¹

The ORFs downstream of ORF VII (I-V, or III-V, depending on splicing of the mRNA; Fig. 72.16) are translated by a different re-initiation mechanism mediated by the

FIGURE 72.16. Genome organization of Cauliflower mosaic virus (CaMV).

Nicked, circular, double-stranded genomic DNA is indicated. Interior circular arrows indicate the most abundant transcripts, with spliced out regions as *dashed lines*. Functions of numbered open-reading frames (ORFs): MP, movement protein; ATP, aphid transmission protein (P2 in Fig. 72.25); VAP, virion-associated protein (P3 in Fig. 72.15); CP, coat protein; POL, RNA-dependent DNA polymerase; TAV, trans-activator of translation.

viral *trans*-activator (TAV) protein, encoded by ORF VI on its own separate mRNA.^{28,239} TAV binds 60S ribosomal subunit proteins L13 and L18 and also translation initiation factor eIF3 which brings the 43S ribosomal ternary complex to the mRNA in normal translation.²³⁹ TAV also recruits the protein kinase target-of-rapamycin (TOR) that becomes hyperactivated leading to phosphorylation of a host factor called reinitiation supporting protein (RISP).²⁸⁸ Normally, when the 40S subunit reaches the start codon, eIF3 is released upon 60S-subunit joining. But TAV, eIF3, phosphorylated TOR, and phosphorylated RISP remain bound to the ribosome during translation elongation and after termination. Presence of these proteins keeps the 40S subunit on the mRNA, and facilitates re-recruitment of the ternary complex and scanning to the next AUG codon where the 60S subunit is recruited and re-initiation takes place.²⁸⁸ This reveals new and complex interactions of ribosomes with mRNAs and new roles for host proteins in translation not known previously.

SUBGENOMIC RNA SYNTHESIS

A key step in gene expression of many positive-strand RNA viruses is RNA-templated transcription of subgenomic mRNAs (sgRNAs).^{214,314} These are usually 3' co-terminal RNAs that permit translation of downstream ORFs of a polycistronic genomic RNA. Examples in the animal kingdom include viruses in the *Nidovirales* order and in the *Togaviridae* family. A much larger portion of the plant virus world generates sgRNAs, including viruses in the *Bromoviridae* (BMV), *Tymoviridae*, *Luteoviridae*, *Tombusviridae*, *Virgaviridae*, *Closteroviridae*, *Flexiviridae* families, and the *Tobamovirus*, *Carlavirus*, *Benyvirus*, *Sobemovirus*, and *Umbravirus*

genera. These viruses have evolved more than one way to generate sgRNAs, and they don't always function as mRNAs.

BMV generates a sgRNA (RNA 4) from the 800 bases at the 3' end of bicistronic RNA 4 (see Fig. 72.6). RNA 4 is the mRNA for the CP. A template-dependent replicase extract, primed with full-length negative-strand genomic RNA extract, was used to demonstrate that RNA 4 is generated by internal initiation of the RdRp at a specific promoter sequence in the negative strand.²¹² It then copies the negative strand until it reaches the 5' end of the template (Fig. 72.17). The RNA structure recognized by the RdRp consists of a core promoter sequence at nts -19 to -1 relative to the initiation site (+1), which contains a short hairpin loop.³⁰⁰ This is preceded (in the 3' direction on the negative strand template) by a 17 nt poly(U) tract (poly(A) in the positive strand) and an A/U-rich tract (Fig. 72.18) that are required for maximal sgRNA transcription.^{314,360} The hairpin may form only upon binding of the replicase in an induced fit process.³⁰¹ It is not needed for replicase binding but is required for sgRNA synthesis. CMV (*Bromoviridae*) uses a very similar promoter,¹⁵⁶ and unrelated TMV and the *Togaviridae* family of animal viruses also generate sgRNAs by internal initiation at promoters containing key primary and secondary structural specificity elements (reviewed in (214,314)).

Viruses in the *Tombusviridae* generate sgRNAs by premature termination (PT) of negative-strand RNA synthesis from the full-length genomic RNA (gRNA) template.¹⁵² In this case, the viral polymerase encounters a highly structured region in the positive-strand template, apparently causing it to terminate negative strand synthesis (see Fig. 72.17). The 3' end of the

FIGURE 72.17. Mechanisms of plant virus subgenomic RNA synthesis. Green sphere, RNA-dependent RNA polymerase (RdRp); blue box, promoter in minus strand; red box, termination signal in plus strand; yellow sphere: exonuclease. **A:** RdRp initiates internally at the promoter in the full-length (–) strand.²¹² **B:** RdRp terminates early during (–) strand synthesis off the genomic RNA template.¹⁸⁴ **C:** An exonuclease degrades genomic RNA from the 5' end until it reaches a structure that blocks further degradation.¹⁴⁵ No RNA replication is needed in this mechanism.

resulting negative strand contains a short promoter sequence resembling the sequence at the 3' end of full-length gRNA. Presumably this is recognized by the replicase that then makes multiple copies of positive-strand RNA by end-to-end copying of the truncated negative strand. This PT mechanism was first indicated by the requirement for a *trans*-acting RNA to synthesize RCNMV sgRNA. The 3' co-terminal CP mRNA is generated from RCNMV RNA 1. Sit et al.³⁰⁵ showed that a loop in RCNMV RNA 2 must base pair to a sequence immediately upstream of the sgRNA start site in RNA 1, in order to generate the sgRNA (see Fig. 72.18). It appears that the viral polymerase terminates negative-strand synthesis when it encounters this bimolecular base paired region. This results

in a 3'-truncated negative strand that serves as a template for positive-sense sgRNA synthesis. By elegantly designed mutations that disrupt and restore base pairing in the positive but not the negative strand (through selective use of G-U base pairs, whose complements, C and A, do not pair in the opposite strand), the White lab demonstrated that, in TBSV and related viruses, long-distance base pairing in *cis* forms a stable structure in the positive strand just upstream of the 5' end of each sgRNA. This base pairing is required for sgRNA synthesis by PT³⁴⁸ (see Fig. 72.18). Various other viruses known or thought to produce sgRNAs by PT are discussed in reference 314.

RCNMV generates a second sgRNA, spanning only the 3' UTR of RNA 1, by a nonreplicative method. This sgRNA, called SR1f, is generated by a host 5'-to-3' exonuclease¹⁴⁵ (see Fig. 72.17). This resembles the mechanism and genome location (3' UTR) of the sfRNA of flaviviruses.²⁴⁴

Some viruses generate 5' co-terminal subgenomic RNAs that lack the 3' end of the genomic RNA. A 5' co-terminal sgRNA, encoding ORF 3 from BMV RNA 3 terminates with a poly(A) tail derived from the intergenic oligo(A) tract in BMV RNA 3.³⁶¹ It may serve as a more efficient mRNA for the BMV 3a movement protein than full-length RNA 3. Viruses in the *Closteroviridae*, which resemble *Nidovirales* in genome organization but are not classified in *Nidovirales*, produce many 3' co-terminal sgRNAs (Fig. 72.19). Like the *Toroviridae* family, and unlike *Coronaviridae* and *Arteriviridae* (all families in *Nidovirales*), the 3' co-terminal sgRNAs of *Closteroviridae* do not contain sequences derived from the 5' end of the genome.³³⁹ Unlike any known nidovirus, Citrus tristeza closterovirus generates two 5' co-terminal sgRNAs with 3' truncations, as well as the expected nested 3' co-terminal sgRNAs that serve as mRNAs for the downstream ORFs. One of the 5' sgRNAs is produced by premature termination (PT) at a stem-loop structure,¹¹⁹ the other by the process of assembly by the minor coat protein.¹²⁰ The roles of these RNAs in infection are unknown. They are not necessary for virus replication in protoplasts.¹¹⁹

In addition to serving as mRNAs, some sgRNAs serve as *trans*-regulators of viral, and possibly host, gene expression. The SR1f RNA of RCNMV and sgRNA2 of BYDV both correspond to the 3' UTR and inhibit translation *in trans*.^{145,297} Because both of these sgRNAs contain a BTE that binds the eIF4G subunit of the limiting translation initiation factor eIF4F with high affinity,³²² they probably inhibit translation by sequestering this key translation initiation factor. This binding allows sgRNA2 to tilt the balance of translation of the two BYDV mRNAs, genomic RNA (gRNA) and sgRNA1, in favor of the latter,²⁹⁷ which is less dependent on eIF4G owing to its less structured 5' UTR (Fig. 72.20). Because the 3' UTR sgRNAs of RCNMV and BYDV also inhibit translation of capped, non-viral mRNAs,^{145,297} it is possible that they globally inhibit host translation, a phenomenon that has not been reported in plant virus infections.

POTYVIRIDAE

About 30% of all plant viruses are in the *Potyviridae* family. *Potyviridae* fall into six genera, with the vast majority of the members in the *Potyvirus* genus. With the exception of genus *Bymovirus*, viruses in *Potyviridae* have one genomic RNA. In the bymoviruses, the same coding capacity is split into two

FIGURE 72.20. Regulation in trans of Barley yellow dwarf virus (BYDV) translation by sgRNA2.²⁹⁷ 1, open-reading frames (ORFs) 1 and 2 are translated from invading genomic RNA to generate the RNA-dependent RNA polymerase (RdRp). 2, replication by the RdRp generates more copies of genomic RNA (gRNA) and three subgenomic RNAs (sgRNA1–3). 3, translation of sgRNA1 produces the coat protein (CP) and movement protein (MP), the former then packages gRNA. 4, simultaneous with step 3, abundant sgRNA2 selectively inhibits translation of gRNA, freeing it for more replication and for encapsidation, and favoring translation of sgRNA1 to produce late functional proteins, such as the CP.

RNAs. Potyviruses employ the highly successful gene expression strategy used by the *Picornavirales*, and many other positive-strand RNA viruses, that is, the genome encodes one large ORF, which is translated as a polyprotein. This polyprotein is co-translationally and posttranslationally cleaved by viral proteases in a controlled manner to produce the functional proteins at the appropriate levels and timing necessary for a productive infection (Fig. 72.21).

Potyviridae also resemble *Picornavirales* in the sequence of the RdRp, and due to the presence of a genome-linked protein (VPg) at the 5' end and a poly(A) tail at the 3' end. However, they differ from the *Picornavirales* because, for example, (a) the virion is a flexuous rod rather than an icosahedron, (b) the coat protein is encoded at the 3' end of the polyprotein ORF rather than the 5' end, (c) the VPg has no homology to the VPg of picornaviruses and probably has different function, and (d) many of the viral proteins have no orthologs in the *Picornavirales*. The inability to infect animals does not necessarily exclude a virus from the *Picornavirales*, as the *Secoviridae* family of plant viruses is a member of the *Picornavirales* order (Fig. 72.22).

Functions of Potyviral Proteins

The N-terminal protein (P1) of the polyprotein is a serine protease that cleaves itself from the adjacent protein HC-Pro. In genus *Ipomovirus*, which lacks HC-Pro, P1 is a suppressor of antiviral silencing.^{207,330} In genus potyvirus, HC-Pro is a powerful silencing suppressor⁷ and has many other functions. HC-Pro functions include: (a) a papain-like cysteine protease that rapidly cleaves the junction with the downstream protein P3,⁴⁸ (b) the helper component required for aphid transmission, serving as the “glue” to attach the potyvirus particle to the interior wall of the aphid stylet,^{13,22,24,25} (c) a role in RNA amplification and systemic movement,^{160,277} (d) a powerful

suppressor of host gene silencing¹⁵⁹ that binds the small interfering RNA,¹⁷² and (e) a component of amorphous cytoplasmic inclusion bodies in cells infected by certain potyviruses, such as Papaya ringspot virus.²⁷³

P3 is the least understood potyviral protein. It has been identified as a symptom and avirulence determinant. Point mutations in Turnip mosaic virus (TuMV) P3 affect ability to infect certain Brassica species,¹⁵⁰ and in P3 of Soybean mosaic virus (SMV) allow infection of normally resistant soybean lines,¹²⁸ but its biochemical function is unknown. A small (60 to 100 codon) ORF, *pipo*, overlaps with the middle portion of the P3 coding region⁵⁷ (Fig. 72.21). It appears to be expressed as a trans-frame fusion with the N-terminal half of P3, to form a protein called P3N-PIPO. Mutations in *pipo* impair potyvirus infectivity on whole plants but permit replication in individual cells, suggesting it plays a role in cell-to-cell movement of the virus.^{55,355} P3N-PIPO interacts with the potyviral cylindrical inclusion (CI) protein and localizes to the plasmodesmata, consistent with a role in virus movement.³⁵⁴ The 6-kD protein immediately downstream of P3, 6K1, usually remains part of P3 due to delayed or incomplete proteolytic cleavage at the P3-6K1 junction, and includes a pathogenicity determinant in Plum pox virus (PPV).²⁸³ Therefore, three P3-derived proteins exist in infected plants, all with the same N-terminus but different C termini: P3N-PIPO, P3, and P3-6K1.

The CI protein is the main component of striking pinwheel or cylindrical structures in the cytoplasm and an ATP-dependent RNA helicase required for RNA synthesis.⁴⁹ It appears to facilitate cell-to-cell movement with help from the coat protein (CP)⁴⁹ as it localizes to, and increases size exclusion limit of, the plasmodesmata, which are necessary for movement of the viral RNP between cells.^{275,277,354} As might be expected of a protein with such crucial functions, CI protein is also a symptom determinant and mutations in the CI coding region can allow potyviruses to break resistance.^{2,374}

The 6-kD 6K2 protein plays a key role in transporting the replication machinery from the ER, where it is translated, to the chloroplast membrane where replication takes place in vesicles.^{272,285,320} This process involves COPII-mediated transport to the Golgi apparatus from which it is transported to the chloroplast membrane via actin filaments.³⁵³ NIa is cleaved into two proteins, the 21-kD genome-linked protein (VPg)

and a 27-kD protease (molecular weights are those of Tobacco etch virus, TEV). The VPg (a) binds eukaryotic translation initiation factor 4E (eIF4E),^{12,177,178,362} (b) serves as the primer for viral RNA synthesis via uridylation of a specific tyrosine residue by the RdRp (NIb),^{8,251} (c) contains a nuclear localization signal (NLS),^{261,284} (d) is associated with membranes, as expected for a replication protein,¹²⁶ (e) is necessary for cell-to-cell movement,²⁸⁶ (f) contributes to suppression of gene silencing,²⁶² and (g) controls phloem loading,²⁶² and (h) affects disease symptoms and resistance breaking.^{2,12,163}

Nuclear inclusion protein, NIb, is the viral RdRp. NIb interacts with NIa in order to catalyze uridylation of the VPg, which presumably primes RNA synthesis in a manner similar to the VPg of picornaviruses.²⁵¹ The role of NIb in the nucleus is unknown, as RNA replication takes place in cytoplasmic membranes.^{59,353}

In addition to forming the virion, the CP also has been implicated in cell-to-cell movement. An aspartate-alanine-glycine (DAG) motif on the surface of the CP is required for aphid transmission, as it binds the HC-Pro protein, which provides the “glue” to attach the virion to the aphid stylet (see details under vector transmission of plant viruses).

VPg-Translation Factor Interactions and Host Resistance

We will expand on the role of the interaction of the VPg with eIF4E because it appears to be the step that is inhibited in most natural resistance genes to potyviruses. About one-half of known plant virus resistance genes are recessive.³²⁴ The sequenced recessive resistance genes against potyviruses encode alleles of the cap-binding translation initiation factor, eIF4E, or the related protein, eIFiso4E.^{274,324} These mutant factors confer resistance because they do not bind the VPg efficiently.^{177,370} An obvious role of VPg binding to eIF4E may be to substitute for the role of the 5' cap in recruiting the ribosome to potyviral genomic RNA for translation. Even when present in trans (not covalently attached to viral RNA), VPg enhanced affinity of eIF4F for TEV RNA and increased translation efficiency.¹⁶⁴ However, TEV RNA translates efficiently in the absence of the VPg, via an IRES³⁷³ that interacts with eIF4G.²⁶⁸ Moreover, some mutations in eIF4E that render it unable to initiate translation, still allow it to facilitate replication of Lettuce mosaic potyvirus¹¹³ or Pea seed-borne mosaic virus (PSbMV) potyvirus.¹² Thus, the

FIGURE 72.23. Use of green fluorescent protein (GFP)-tagged virus to monitor plant virus movement in whole plants. Plants were inoculated with tobacco mosaic virus (TMV) engineered to express GFP. **Panels A–C** indicate increasing times post inoculation. *Arrowheads*, inoculated leaves; *arrows*, systemically infected, non-inoculated leaves. Plants are shown under UV light. Chloroplasts in uninfected tissue fluoresce red. (Reprinted with permission from Niehl A, Heinlein M. Cellular pathways for viral transport through plasmodesmata. *Protoplasma* 2011;248:75–99.)

eIF4E-VPg interaction must play other, more essential roles in virus infection than translation stimulation.

CELL-TO-CELL MOVEMENT OF PLANT VIRUSES

Plant virus infections initiate at one or a few cells, from which the virus must spread systemically throughout the plant (Fig. 72.23). However, the plant cell wall is an excellent barrier to infection by all pathogens. Even if the cell wall is penetrated,

for example by an aphid stylet (below), to permit virus entry, the infection often remains confined to a single cell and is aborted because the virus cannot escape. But plant cells must remain in contact with each other and they do so via intercellular tunnels through the cell wall called plasmodesmata. It is this connection that viruses exploit to move from cell to cell. The walls of the plasmodesmata are lined with the plasma membrane, which is contiguous between neighboring cells. The endoplasmic reticulum, which spans the plasmodesmata in the form of the desmotubule, and the cytoplasm are also contiguous from one cell to the next (Fig. 72.24A). Plasmodesmata

FIGURE 72.24. Diagrams of two different mechanisms of plant virus movement to new cells. **A:** A normal plasmodesma. **B:** A plasmodesma containing an MP tubule from the tubule-expressing virus, GFLV. **C:** Movement of nontubule-forming virus tobacco mosaic virus (TMV).²³¹ Proteins involved in virus-induced plasmodesmata modification are indicated at right. (Reprinted with permission from Niehl A, Heinlein M. Cellular pathways for viral transport through plasmodesmata. *Protoplasma* 2011;248:75–99.)

allow movement of small molecules between cells by diffusion. Normally, the size exclusion limit (SEL) is too small to permit macromolecules such as nucleic acids or proteins to fit through plasmodesmata, but mRNAs encoding certain non-cell-autonomous proteins are transported selectively through plasmodesmata.^{198,199} Plant viruses encode movement proteins (MPs) that increase the size exclusion limit and specifically transport the viral RNP through the plasmodesmata to adjacent cells.

Many different viral cell-to-cell movement mechanisms have evolved. (See 232,327,338 for excellent reviews.) Viral MPs either leave plasmodesmata intact but modify it to permit viral RNP transport, or they obliterate much of the plasmodesmatal structure by formation of a tubule, through which intact virions move. A partial list of virus movement mechanisms includes: (a) the 30K protein of TMV and related viruses, (b) the triple gene block of Potex-, Hordei-, Carmo-, and other virus genera,³³⁷ (c) the quintuple gene block of *Closteroviridae*, (d) coordinated nuclear shuttle and cell-to-cell movement by two proteins of *Geminiviridae*, and (e) tubule formation, by diverse RNA viruses in the *Secoviridae*, *Tospoviridae*, *Ilarviridae* and *Bromoviridae*, and DNA viruses in the *Caulimoviridae* and *Badnaviridae* families.

The “30K-type” movement protein (MP) found in TMV is a single-stranded nucleic acid-binding protein⁵⁸ that increases the SEL of plasmodesmata³⁶³ and interacts with microtubules that may direct the viral genome to the plasmodesmata¹³⁶ (Fig. 72.24C). Interactions with calreticulin, pectin methylesterases, and DnaJ chaperones are also thought to participate in transport of the MP and its viral genome cargo to the plasmodesmata.³²⁶ The plasmodesmal pore size is increased by interaction of MP with an ankyrin protein that decreases callose levels around the neck of the plasmodesma.³²⁷ Citovsky and colleagues propose that the diameter of the plasmodesma is gated by callose.³²⁷ Lower levels of callose would increase the SEL and permit virus movement through the plasmodesma. MP also increases the levels of callose-degrading enzyme beta-glucanase and cell wall-degrading enzyme pectin methylesterase in the plasmodesmata, both of which are expected to increase the SEL. These processes may be regulated by calcium ion concentration²³¹ either via regulation of signaling pathways or by direct effect on beta glucanase activity. Increases in calcium levels have been shown to decrease SEL.¹³⁹

Potexviruses, hordeiviruses, pomoviruses, pecluviruses, benyviruses, and carmoviruses use a “triple gene block” suite of three proteins, TGBp1, TPBP2, and TGBp3, to facilitate cell-to-cell movement. TGBp1 is about 25 kD and is translated from a subgenomic mRNA. Like the TMV MP, TGBp1 increases the SEL, and binds and transports the viral RNA throughout the plasmodesmata. TGBp1 of potexviruses can move between cells on its own, whereas TGBp1 of the other genera listed above requires TGBp2 and TGBp3. TGBp2 and TGBp3 are also necessary for cell-to-cell movement but they do not move between cells. TGBp2 (~12 kD) and TGBp3 (~7 kD) are translated from overlapping ORFs on the same subgenomic RNA. The TGBp3 ORF requires leaky scanning for translation and thus accumulates to much lower levels than TGBp2. Both proteins associate with virus-induced vesicles in the ER and deliver the TGBp1-viral RNA RNP to the plasmodesmata.³³⁷ Although the TGB proteins appear similar in size and expression mechanism, their functions are quite diverse among the different viruses that use the triple gene block strategy. Like TMV MPs, TGB MPs reach the plasmodesmata via

the microtubules, and some potexvirus TGBps increase levels of beta glucanase in the plasmodesmata.³³⁷

Geminiviruses (*Geminiviridae*) have circular single-stranded DNA genomes and twin icosahedral (geminata) particles. Most geminiviruses fall in genus *Begomovirus*. Begomoviruses have two genomic DNAs of 2.5 to 2.8 kb. The other geminivirus genera have only one genomic DNA of the same size. Begomoviruses express two proteins that move the genome intracellularly and intercellularly.¹⁷⁵ After genome replication in the nucleus, the nuclear shuttle protein (NSP) moves the new genome copies out of the nucleus. In the cytoplasm, the movement protein (MP) binds the NSP-DNA complex and transports it through the plasmodesmata in ER-derived tubules (not MP-derived tubules) to adjacent cells. The NSP then delivers the viral DNA to the nucleus of the new cell for more rounds of replication.¹⁷⁵

The MP of Cabbage leaf curl virus (CaLCuV) binds the plant synaptotagmin protein, SYTA.¹⁷⁹ Virus movement was delayed and restricted in SYTA knockout lines of *Arabidopsis*, and overexpression of dominant negative mutants of SYTA inhibited movement of CaLCuV as well as TMV, indicating that TMV may also require SYTA for movement.¹⁷⁹ Confocal laser scanning microscopy of GFP-tagged SYTA mutants indicated that SYTA regulates endocytosis and endosome recycling. Therefore, the MPs of begomoviruses and tobamoviruses appear to transport their DNA and RNA viral genomes, respectively, to the plasmodesmata by an endocytic recycling pathway.¹⁷⁹ Synaptotagmins are regulated by calcium ion. This supports a common theme of calcium regulation of proteins associated with plant viral cell-to-cell movement.

Tubule-forming MPs form a hollow shaft through the plasmodesma, eliminating the desmotubule and disrupting the intercellular ER connection (Fig. 72.24B). These MPs bind viral RNA weakly, if at all, necessitating movement of the viral genome in the encapsidated form.²³¹ The MP of Grapevine fanleaf virus (GFLV) is delivered to the plasmodesma via the secretory pathway.¹⁷⁴ The MPs of GFLV, an RNA virus, and CaMV, a DNA virus, form tubules by interacting with plasmodesmata-localized proteins (PDLPs). Any one of three different PDLPs is necessary and sufficient for efficient tubule formation.⁶ *Arabidopsis* plants harboring knockouts of all three PDLPs reduced GFLV tubule formation by about 50% and slowed spread of infection by GFLV or CaMV. However, both viruses still managed to infect and move at significant levels, indicating that movement, albeit at a slower rate, can take place in the absence of the PDLPs.⁶

Finally, as with so many other examples in this review, understanding of plasmodesmal transport of macromolecules pioneered in plant virology may provide valuable insight into mammalian cell biology. Relatively recently, intercellular trafficking connections called tunneling nanotubes have been discovered in animal cells.¹⁰³ They may share many functions and mechanisms with plasmodesmata.

VECTOR TRANSMISSION OF PLANT VIRUSES

Because plants are sessile organisms, plant viruses are more dependent than animal viruses on vectors for transmission from host to host.¹²² Few plant viruses are transmitted vertically through seed, and for those few seed-transmitted viruses, seed transmission is a rare stochastic event. The large majority

of plant viruses rely on aphids, whiteflies, or leafhoppers for plant-to-plant transmission.^{137,228} All of these insects are in the order *Hemiptera*, and are sap-sucking insects that feed on the vascular system of the plant. Thrips (order *Thysanoptera*), especially *Frankliniella occidentalis*, are important vectors because they transmit TSWV, a bunyavirus with a vast host range and worldwide distribution.³⁵⁹ Beetles, mites, nematodes, fungi, and humans also serve as vectors of some important plant viruses. Humans, via agricultural equipment, are the only known vectors of most viroids. Therefore, it has been speculated that viroid diseases did not exist before agriculture.

Here we will focus on hemipterans, the mosquitoes of the plant world. Hemipterans feed directly on the phloem, using the feeding structure called the stylet. When a hemipteran lands on a plant, it inserts the stylet between plant cells until it penetrates the phloem cells, where it spends its life feeding on the sugar-rich, protein-poor plant sap. Aphids usually lack wings, and reproduce parthenogenetically. Therefore, during the summer aphids accumulate clonally to huge numbers and all are female. When populations reach high levels or are stressed, new progeny will be winged and fly to neighboring plants, or reach the high altitude winds on which they can travel hundreds of kilometers.³⁷⁷ Therefore, certain aphid-transmitted plant viruses can be transmitted long distances depending on weather patterns.

Aphids and other hemipterans transmit viruses by a variety of mechanisms.³⁴ These have been termed nonpersistent, semipersistent, and persistent.^{122,137,228,229} Nonpersistently transmitted

viruses are acquired rapidly and are carried by the vector for only a period of minutes or hours. However, this is sufficient for such viruses to spread efficiently in the field. Potyviruses and the unrelated CMV are nonpersistently transmitted. Virions of potyviruses and CMV adhere to the distal end of the aphid stylet in order to be transmitted (Fig. 72.25).

Potyviruses rely on the multifunctional HC-Pro protein (HC is the abbreviation for helper component for aphid transmission) to act as a bridge or glue to bind the virion to the aphid stylet. HC-Pro is a nonstructural protein, acquired by the aphid from the infected cell.³²¹ The N-terminus of HC-Pro, including a conserved stylet-binding motif, KITC, is required for binding of PVY HC-Pro to the stylet, but not to the virion.²⁴ Overlay binding assays have revealed different putative receptor proteins in the aphid stylet that interact with HC-Pro. These include a group of four aphid cuticular proteins⁷⁸ and ribosomal protein S2 (RPS2).⁹² RPS2 has greater than 60% sequence identity to the RPS2/laminin receptor in humans, a known receptor for diverse mammalian viruses and prions. Lysine to glutamate mutations in the stylet binding motif of HC-Pro prevented binding to the cuticle proteins and to RPS2, supporting a specific role for these proteins in aphid transmission.⁹² On the CP side of the interaction, a highly conserved motif, aspartate-alanine-glycine (DAG) in the potyviral CP is required for aphid transmission of most potyviruses,¹⁴ and is required for HC-Pro-binding to the virion.²⁵

FIGURE 72.25. Nonpersistent (left) and semipersistent (right) transmission of viruses by aphids. Semipersistent transmission of CaMV was thought to involve binding of the virion (via nonstructural proteins P2 and p3) to the foregut, but p2 was shown to bind only to the common duct at the tip of the stylet. (Reprinted with permission and modified from Ng JC, Falk BW. Virus-vector interactions mediating nonpersistent and semipersistent transmission of plant viruses. *Annu Rev Phytopathology* 2006;44:183–212.)

In contrast to potyviruses, CMV requires no helper component for aphid transmission (Fig. 72.25). The virion binds the stylet directly. A highly acidic, aspartate-glutamate-rich tract in the β H- β I loop of the capsid protein is required for aphid transmission.¹⁹⁰ This may be the site that binds the stylet. To our knowledge, a candidate host binding site or receptor has not been identified for CMV.

Semipersistently transmitted viruses are acquired within minutes to hours of feeding and are retained by the vector for hours to days. Examples of semipersistently transmitted viruses include CaMV (*Caulimoviridae*) and Lettuce infectious yellows virus (LIYV, *Closteroviridae*) (Fig. 72.25). CaMV relies on two nonstructural proteins to attach to the stylet. These include the viral protein P3, which dimerizes to form the digitation domain. Viral protein P2 forms a bridge between the P3-virion complex and the wall of the aphid stylet. Although semipersistently transmitted viruses were thought to bind the foregut, Uzest et al.³²⁹ showed that the P2 protein of CaMV binds only to the extreme tip of the stylet in the common duct, in a previously undescribed anatomical structure they call the acrostyle.³²⁸ Therefore the P3-virion complex is found only there. Other semipersistently transmitted viruses, such as LIYV, bind more proximally in the stylet and foregut. Like other closteroviruses, the long flexuous rod-shaped virion of LIYV contains a few copies of a minor coat protein (CPm), located only at one end of the flexuous rod-shaped virion. This CPm is thought to bind directly to a receptor in the foregut of its whitefly vector.²²⁸ In summary, the helper component mechanism or the direct virion binding mechanism of attachment of the virion to the aphid mouthparts can apply to either semipersistent or nonpersistent transmission strategy.

Persistent transmission can be either circulative, in which the virus circulates through, but does not replicate in, the vector, or propagative, in which the virus replicates in the vector. Circulative transmission is far more common, as viruses in the *Luteoviridae*, and large *Geminiviridae* families are transmitted in this manner by aphids¹²¹ and whiteflies,^{153,223} respectively. These are unlike mammalian arboviruses, all of which replicate in their vectors. In fact, the few plant viruses that undergo propagative transmission, closely resemble mammalian arboviruses. For example, TSWV, which replicates in its thrips vector,⁶⁵ is a member of the *Bunyaviridae* family. Plant reoviruses⁹⁹ and rhabdoviruses²⁶⁹ also replicate in their insect vectors. In contrast, the *Luteoviridae* and *Geminiviridae* are distinct families with no close relatives in the animal virus world.

Circulative transmission is best characterized in the luteoviruses. Luteovirus virions, which accumulate only in the phloem, are acquired by the feeding aphid and transported into the aphid hindgut, or occasionally foregut, depending on the virus, without being digested. They cross into epithelial cells by receptor-mediated endocytosis in clathrin-coated vesicles and are then ejected into the hemolymph (blood stream) where they circulate¹¹⁵ (Fig. 72.26). They then enter the accessory salivary gland through another endocytosis process.¹¹⁶ Upon feeding, the aphid salivates, ejecting virions, along with saliva, into the phloem cells.

The *Luteoviridae* virion consists of a standard T = 3 icosahedron similar to those of *Tombusviridae* or *Sobemoviridae*. However, unlike those viruses, a small fraction of the *Luteoviridae* CP subunits contain a long C-terminal extension that is translated by readthrough of the CP stop codon³⁹ (see Fig. 72.12). This readthrough domain (RTD) is essential for aphid transmission.³⁵ Its biochemical function is unclear. Viruses lacking the RTD can

FIGURE 72.26. Movement of persistently transmitted luteovirus through the aphid. Arrows indicate path of virions from phloem in plant through the digestive tract and open circulatory system, into the accessory salivary gland (ASG) and out through the salivary canal when aphid feeds on a different plant. Purple hexagon: efficiently transmitted luteovirus particle; blue hexagon, inefficiently transmitted luteovirus particle; green hexagon, nontransmitted luteovirus particle enters the hemolymph but not the ASG; orange hexagon, nonluteovirus particle remains in digestive tract until it is ejected in aphid honeydew. (Modified and reprinted from: Power AG, Gray SM. Aphid transmission of barley yellow dwarf viruses: interactions between viruses, vectors, and host plants. In: D'Arcy CJ, Burnett PA, eds. *Barley yellow dwarf: 40 years of progress*. APS Press, St. Paul, 1995;259–291.)

still replicate in the plant and assemble virions. These virions can even be taken up into the aphid hemolymph after aphids are fed the RTD-lacking virions,²⁷⁰ but the virions are not transmitted by the aphid to other plants.³⁵

The RTD was shown to bind, *in vitro*, to a GroEL-like chaperonin protein called symbionin, which is synthesized in massive amounts by endosymbiotic bacteria (*Buchnera* spp.) in aphids.³³³ This interaction was reported to stabilize the virion in the hemolymph.²⁷⁰ However, the binding does not resemble normal interaction of groEL with proteins,¹³⁸ and recently, the bacteria that produce symbionin were shown to be confined in sealed organelles in the aphid, rendering symbionin inaccessible to virions in the aphid hemolymph.³³ These observations shed doubt on a role for symbionin in aphid transmission. The receptors in the gut epithelium and the accessory salivary gland membranes, to which luteovirus virions are thought to attach, have not been identified. However, a combination

of genetics and biochemical approaches suggests a luciferase and a cyclophilin as potential luteovirus receptors on the accessory salivary gland.³⁶⁸ They play key roles in determining aphid specificity of transmission of Cereal yellow dwarf virus.³⁶⁸

Over 100 viruses in genus *Begomovirus* (*Geminiviridae*) are transmitted in a circulative manner by a single whitefly species: *Bemisia tabaci*.¹⁵³ Therefore, *B. tabaci* is probably the most economically important vector species in all of agriculture, worldwide.²²³ The general mechanism of circulative transmission of *Geminiviridae* is thought to follow a similar process as that of the *Luteoviridae*, but the twinned geminivirus particles lack the readthrough domain required for luteovirus transmission. In contrast to the *Geminiviridae*, *Luteoviridae* are transmitted by dozens, if not hundreds, of aphid species, and the relationship between virus and aphid can be highly specific. For example, different BYDV and CYDV viruses were first differentiated by their preferred aphid vector.¹²¹ Even different biotypes of one aphid species can have very different efficiencies of transmitting a particular BYDV or CYDV isolate.³⁶⁸

VIROIDS AND SATELLITE RNAs

Viroids

Viroids are noncoding, single-stranded, circular RNAs that are unique to plants. For an excellent history of the discovery of these remarkable infectious agents, see the review by T.O. Diener.⁷² Viroids range from about 220 to 400 nt long, and most fold into rod-shaped secondary structures with small single-stranded regions, whereas some form branched structures (Fig. 72.27). They encode no proteins and are not packaged in virions. Viroids fall into two families, the *Pospiviroidae* (named for Potato spindle tuber viroid, PSTVd) and the *Avsunviroidae* (named for Avocado sunblotch viroid, ASBVd). The former replicate in the nucleus, whereas the latter replicate in the chloroplast. Both RNAs replicate by a rolling circle mechanism that generates multimeric progeny RNAs, which are cleaved and ligated to generate new circular viroids⁹⁴ (Fig. 72.28).

Viroids rely entirely on host proteins for replication and movement in the plant.⁷⁵ DNA-dependent RNA polymerase II is “fooled” into recognizing RNA of the *Pospiviroidae* and

FIGURE 72.27. Structures of viroids. **A:** Both strands of Avocado sunblotch viroid (ASBVd) showing self-cleavage sites and transcription initiation sites. Note that neither hammerhead ribozyme that performs self-cleavage is formed in the most stable structure shown here. **B:** Secondary structure and functional domains of potato spindle tuber viroid (PSTVd). Transcription initiation site, and hairpins I and II (HPI' and HPII') do not form in the stable rod-shaped structure. **C:** Hairpins formed by HPI and HPII sequences for cell-to-cell movement. FIGURE 72.28. Rolling circle replication mechanism of viroids and some satellite RNAs. Infectious strand is defined as + strand (dark line). Triangles indicate cleavage sites. **Left column:** symmetrical replication mechanism in which multimeric minus-strand generated by rolling circle copying of plus strand is cleaved into monomers and circularized prior to serving as template for plus-strand synthesis. **Right column:** asymmetrical replication mechanism in which minus strand remains uncleaved and the multimeric form serves as template for plus-strand synthesis.

serves as the viroid replicase.²⁵⁶ A specific domain in the viroid RNA serves as origin of replication.¹⁶⁸ A different domain, loop 6, is required for cell-to-cell movement³¹⁵ (see Fig. 72.27). *Positiviridae* require an RNase III-type enzyme for cleavage and an as-yet unidentified ligase, other than tRNA ligase, for ligation.¹⁰⁹ In contrast, the *Avsunviridae* contain hammerhead ribozymes in both strands that self-cleave the multimers into monomers.⁹³ It is important to note that viroids and satellite

RNAs form metastable structures: the same sequence folds to form different structures, each of which has a different function, at different stages of the replication cycle (see Fig. 72.27). For example, two hairpin loops, not formed in the native viroid rod, are essential for PSTVd replication.²⁹³

Satellite RNAs

In contrast to viroids, satellite RNAs and satellite viruses depend on a helper virus for replication and cell-to-cell movement. Satellite viruses encode their own coat protein gene, distinct from the helper virus. For example Satellite tobacco necrosis virus (STNV) encodes a CP that packages only the 1260 nt STNV RNA in a T = 1 virion, whereas the helper virus, TNV, which replicates both its own 5-kb RNA and STNV RNA, packages only TNV RNA in a T = 3 virion made of TNV and not STNV CP subunits.¹⁵⁴ Satellite tobacco mosaic virus differs even more from its helper by forming a spherical virion, whereas TMV, of course, forms rods.³³¹

Satellite RNAs, in contrast to satellite viruses, do not encode CP. They rely on the helper virus for replication and encapsidation. Satellite RNAs come in two varieties: linear-only RNAs, and viroid-like RNAs that replicate via the rolling circle mechanism (Fig. 72.28). The viroid-like satellite RNAs have no ORFs, but some linear satellite RNAs encode non-structural proteins. For example, the satellite RNA of Bamboo mosaic virus encodes its own movement protein.³³⁸ In contrast, the linear satellite CMV RNA encodes no proteins.

Satellite CMV RNA was discovered by its severe effect on symptoms caused by CMV.³³¹ In 1972, the tomato crop in Alsace was decimated by a CMV outbreak, with far more severe symptoms than usual. The culprit turned out to be a satellite RNA associated with CMV, originally called CARNA 5, now called satellite CMV RNA.¹⁵⁷ Interestingly, this same virus-satellite combination that is lethal in tomato, attenuates disease symptoms of the helper virus in most hosts (Fig. 72.29).³⁵² The simplest explanation for attenuation is that, like a defective interfering (DI) RNA, satellite RNA competes for the helper virus' replication machinery, reducing levels of the helper virus. However, recently it has been observed that the high levels of satellite RNA induce a strong antiviral RNAi response, which would attenuate virus replication and disease symptoms.¹⁴⁰ In contrast, the Y-satellite RNA of CMV causes bright yellowing symptoms in tobacco, because a small RNA generated from it by the host RNAi machinery, fortuitously has homology to the chlorophyll biosynthetic gene, *ChlI*. This results in host degradation of its own *ChlI* gene, which in turn causes bright yellow symptoms.^{101,299,306} Consistent with this observation, plants transformed with a viral silencing suppressor that reduced the host antiviral response, showed much milder symptoms upon infection with CMV and satellite RNA.³⁴⁶

Like viroids, viroid-like satellite RNAs replicate by a rolling circle mechanism, but replication takes place in the cytoplasm and is carried out by the helper virus' RNA-dependent RNA polymerase. The RdRp presumably recognizes an origin of replication, then it copies the circular "positive" strand RNA (the strand that is encapsidated), to make multimeric negative strands. In some satellites, this multimer serves directly as template for synthesis of multimeric positive strands⁶⁴ (see Fig. 72.28, right). In other satellites, the multimeric negative-strand self-cleaves at either a hammerhead or a hairpin ribozyme, and then is circularized by ribozyme or host

(C reprinted with permission from Shimura H, Pantaleo V, Ishihara T, et al. A viral satellite RNA induces yellow symptoms on tobacco by targeting a gene involved in chlorophyll biosynthesis using the RNA silencing machinery. *PLoS Pathogens* 2011;7:e1002021.) Top, tomato; middle, pepper; bottom, maize. Notice that CMV satellite RNA greatly exacerbates symptoms in tomato, but attenuates symptoms in pepper and maize.

ligase activity⁴⁰ (see Fig. 72.28, left). This circular negative strand then serves as template for production of multimeric positive strands. The positive-strand multimers self-cleave at a hammerhead ribozyme site. Some are then ligated into circles before packaging in the virion along with helper virus genomic RNA. In others, the linear cleaved RNA is encapsidated, with monomers being most abundant, but linear dimers, trimers, and so on, are also present.²¹³ These RNAs are circularized upon disassembly of the virion as it invades the cell. Like viroids, the viroid-like satellite RNAs form different structures to perform different functions throughout the replication cycle.^{51,307} Like linear satellite RNAs, viroid-like satellite RNAs usually reduce symptoms caused by the helper virus. As a result, transgenic expression of satellite Tobacco ringspot virus RNA can serve as a resistance gene.¹¹²

Satellite RNAs differ from defective interfering (DI) RNAs in that DI RNAs contain sequences derived from the helper virus, whereas satellite RNAs have no sequence homology to the helper.³⁰² Because DI RNAs harbor the replicase recognition site(s) from the helper virus,³⁵⁷ it is obvious how they compete with helper viral RNA for the RdRp. It is less obvious how the helper virus RdRp recognizes the satellite RNA, which bears no sequence or obvious structural similarity to the helper. It may be that this difference allows the satellite to be an even more efficient template than the helper virus RNA.

Understanding viroid and satellite RNA replication has led to a better understanding of hepatitis δ virus (HDV) RNA, which was discovered more recently.⁹⁴ Like many viroids, HDV RNA is replicated by host DNA-dependent RNA polymerase and uses a rolling circle replication mechanism that is dependent on ribozyme self-cleavage. It differs in that it is much larger than the plant satellites and viroids and it encodes a protein, delta antigen, in its negative strand. HDV has been proposed to be a fusion of a viroid and an mRNA,³⁶ which would be the first example of a plant virus or viroid providing some of the starting material for evolution of a human pathogen.

HOST DEFENSES AND VIRAL COUNTERMEASURES

The responses of host plants to viruses are determined by the interactions of viral proteins and nucleic acids with host factors as well as host surveillance systems that protect plant cells against virus infection. Resistance to viruses can be determined by specific recognition that is mediated by dominant resistance (R) genes, by recessive resistance genes that include defective host factors, or by RNA silencing. The recessive resistance mediated by alleles of *eIF4E* and *eIFiso4E* was discussed in the section on potyviruses. Here we focus on dominant resistance genes and RNA silencing.

Dominant Resistance Genes

Dominant, monogenic virus resistance traits mediate defense against specific strains of a virus species, an entire virus species, or several virus species within a genus. The *N* gene of tobacco is an example of an *R* gene with broad specificity, because it confers resistance to all tobamoviruses except the Ob strain of TMV.²³⁵ *R* gene-mediated resistance is frequently accompanied by (a) programmed cell death, (b) induction of reactive oxygen species, (c) induction of defense-related proteins, (d) accumulation of the phytohormone salicylic acid, (e) accumulation of defense-related secondary metabolites, and (f) fortification of cell walls. These concomitant events are known collectively as the hypersensitive response (HR) that is accompanied by the appearance of macroscopic necrotic lesions (local lesions) at the site of inoculation. Another form of induced resistance to viruses is extreme resistance. It is also mediated by *R* genes, but the plants do not display local lesions and remain symptomless. Genes that confer extreme resistance prevent virus replication and movement in initially infected cells. A virus strain that is recognized by an *R* gene is said to be avirulent. In many cases, it has been possible to map the particular amino acids in viral proteins that determine recognition by *R* genes. This is typically accomplished by exchanging domains of viral strains that differ in their abilities to infect a plant carrying the *R* gene. Frequently, a single protein such as replicase, movement protein, VSR, or coat protein is the avirulence determinant.^{47,308} However, the avirulence determinant may be more complex for some resistance traits. For example, the HC-Pro and P3 proteins of Soybean mosaic virus are both involved in recognition by *Rsv1* in soybean.^{85,127,128,356}

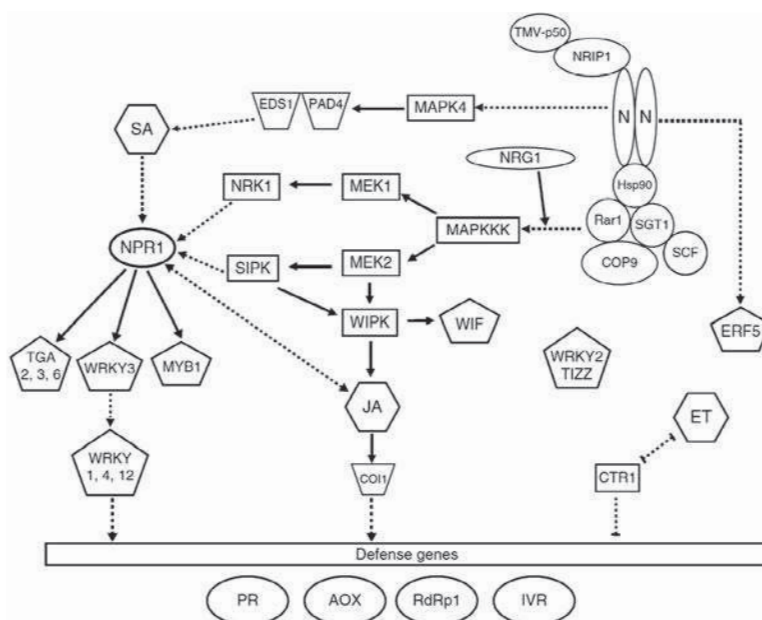

The dominant-resistance genes that mediate HR or extreme resistance and have been cloned fall into a large class known as nucleotide binding site leucine-rich repeat proteins (NB-LRR).^{47,98,308} These proteins can be further subdivided into the TIR-NB-LRR and CC-NB-LRR subclasses based on the sequences at their amino termini. The TIR-NB-LRR proteins have similarity to the cytoplasmic domains of the Toll and

Interleukin-1 receptors, whereas amino termini of CC-NB-LRR proteins are predicted to have a coiled-coil structure. The complete mechanism by which these proteins signal is not understood. The most work has been done with the *N* protein (a TIR-NB-LRR) that recognizes the TMV RdRp (Fig. 72.30), and the *Rx1* protein (a CC-NB-LRR) that recognizes the PVX coat protein.

There are two basic models for how plant *R* proteins recognize pathogens, including viruses. The ligand-receptor model posits that the *R* protein, and the component of the virus that is recognized, interact directly. Alternatively, in the guard model, the *R* protein monitors the status of a host protein that interacts with—or is a target of—a viral protein. Therefore, the *R* protein indirectly detects the presence and activity of the viral protein. The guard model has been demonstrated for the *N*-TMV interaction and the *Rx1*-PVX interaction. The TIR domain of *N* interacts with a pre-recognition complex containing a chloroplast protein named NRIP1 (N receptor-interacting protein) and the TMV replicase.^{43,46} Subsequently, *N* may oligomerize via its TIR domain,²¹⁰ and then localize to the nucleus.^{43,46} Localization to the nucleus is required for *N*-mediated resistance,⁴³ suggesting that activated *N* reprograms transcription.²³⁶ *N* function also involves the interaction of its LRR domain with HSP90, which recruits the co-chaperones RAR1 and SGT1.^{191,197,242} RAR1 and SGT1 in turn recruit the COP9 signalosome.¹⁹² Recognition of the NRIP1-TMV replicase interaction by *N* activates downstream signaling networks that require the phytohormones salicylic acid (SA), jasmonic acid, and ethylene, as well as numerous signal transduction genes including NPR1, MAP kinase cascades, and transcription factors such as WRKY, TGA, and MYB⁴⁷ (see Fig. 72.30).

The CP of PVX is the elicitor of *Rx*-mediated resistance, but its recognition appears to be indirect.²¹⁹ Recognition of PVX CP occurs through the C-terminal region of the LRR domain of *Rx*,²⁵⁸ and this recognition specificity can be altered and extended by mutations within the LRR domain.⁹¹ Intramolecular interactions between CC and NBS-LRR domains or CC-NBS and LRR domains correlate with an inactive *Rx*

FIGURE 72.30. Model of a virus resistance signaling pathway based on the *N* gene for TMV resistance from tobacco. *N* recognizes the complex of the chloroplast protein NRIP1 bound to the TMV-p50 elicitor portion of the viral replicase protein. The recognition activates a signaling network that is regulated by phytohormones including salicylic acid (SA), jasmonic acid (JA), and ethylene (ET). This network results in increased transcription of defense genes. For details, see text and.⁴⁷ (From Carr JP, Lewsey MG, Palukaitis P. Signaling in induced resistance. *Adv Virus Res* 2010;76:57–121, with permission.)

conformation. In the presence of CP elicitor these interactions are disrupted, providing evidence that Rx is activated when interactions between its C-terminus and LRR are abolished.^{257,258} Rx, like N and other NB-LRR proteins, also requires HPS90, RAR1, and SGT1 for its function.

In host–virus interactions that produce HR locally, there is also typically induction of a secondary defense response in other noninoculated parts of the plant known as systemic acquired resistance (SAR).^{47,308} SAR increases resistance to the pathogen that initially triggered HR and enhances broad-spectrum resistance to a variety of viruses, bacteria, and fungi. SAR is caused by increased accumulation of SA in systemic tissues.³⁴⁰ SA is transported systemically as methyl salicylate (MeSA), which is demethylated in the target leaves, leading to increased levels of SA systemically.²⁴⁰ The accumulation of SA in concert with lipid-based signals activates defenses in the systemic tissues.^{189,341} SA induces accumulation of reactive oxygen species and expression of a set of pathogenesis-related (PR) defense proteins. Currently there is little understanding of how SA-dependent responses mediate antiviral resistance. However, some components of antiviral silencing discussed

below, such as RNA-dependent RNA polymerase 1, are induced by SA, suggesting that SA-mediated defenses and antiviral RNA silencing pathways intersect.⁴⁷ This idea is supported by the finding that the CMV-2b proteins, which suppresses RNA silencing (discussed below), also interferes with SA-mediated defenses in Arabidopsis.¹⁵¹

PTGS—An Inducible, Adaptable Innate Immune Response

One of the major functions of the RNA silencing system in plants and other eukaryotes is to protect cells against foreign, nucleic acid–based invaders including RNA viruses, DNA viruses, and viroids.^{61,76,77,298,303} The importance of RNA silencing in antiviral defense is punctuated by the fact that most, if not all, plant viruses encode suppressors of RNA silencing (VSRs) that function by a variety of different mechanisms.^{44,61,76,77,298}

Key components of the plant antiviral RNA silencing system are Dicer-like (DCL), Argonaute (AGO), and RNA-dependent RNA polymerase (RdRp) proteins (Fig. 72.31). These proteins function in concert to produce and amplify virus-derived small RNAs (vsRNAs) in order to direct degradation or modification

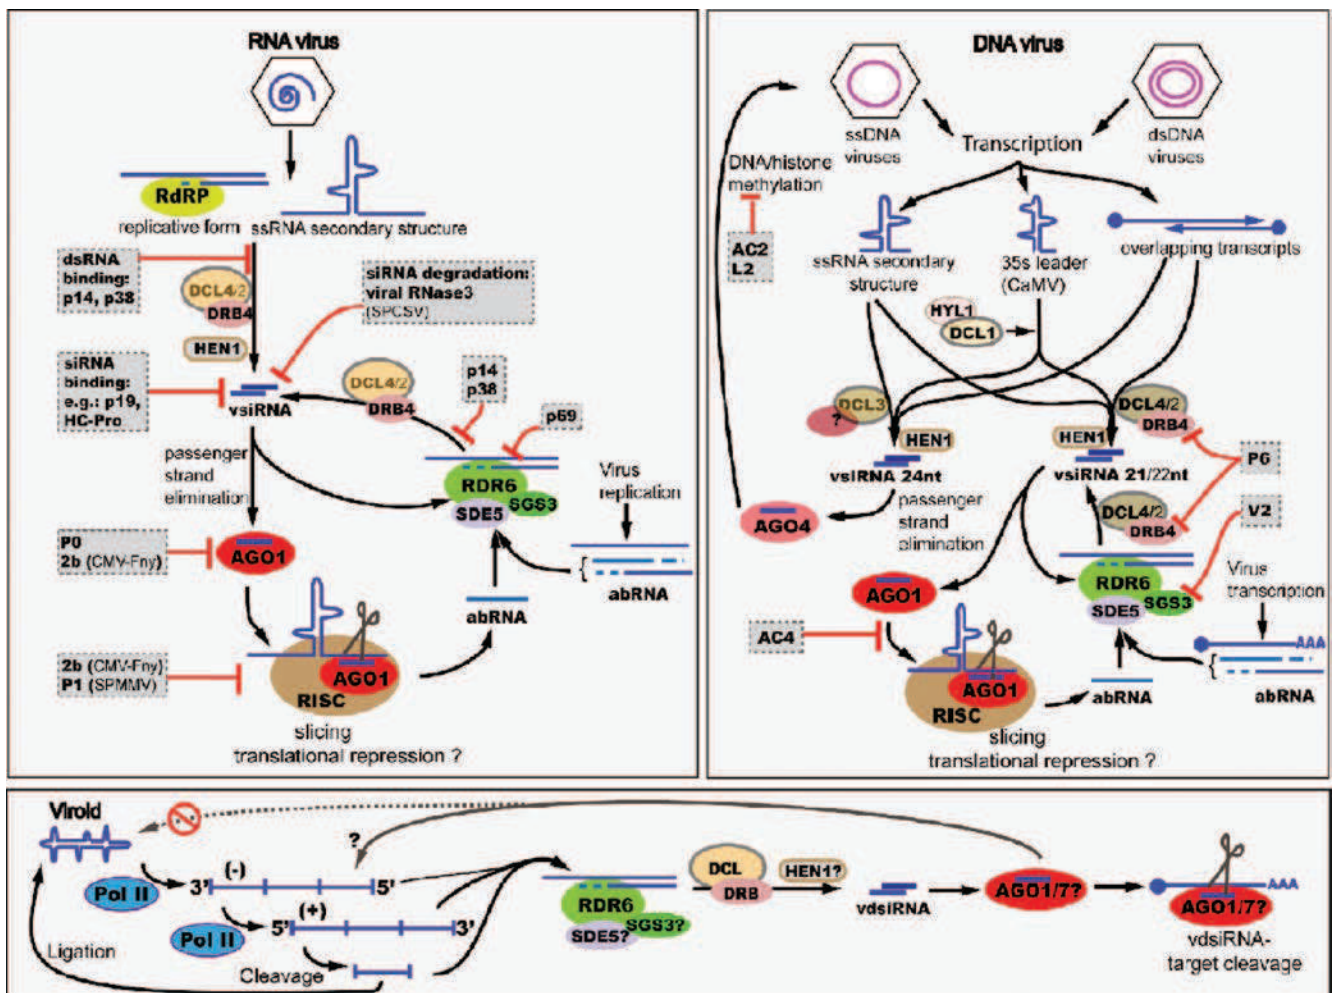

FIGURE 72.31. Antiviral RNA silencing pathways directed against viruses and viroids. Silencing suppressors and their mechanisms are shown in gray boxes. The red bars indicate the points in the silencing pathways in which they interfere. For details, see text. (From Csorba T, Pantaleo V, Burgyn J. RNA silencing: an antiviral mechanism. *Adv Virus Res* 2009;75:35–71, with permission.)

of nucleic acid–based pathogens or inhibit their translation. Unlike the genetic resistance described above, antiviral RNA silencing is adaptive because RNA silencing is initiated by dsRNA, irrespective of origin and sequence.

The mechanisms of antiviral RNA silencing have been investigated in most detail in the model plant, *Arabidopsis thaliana*. *Arabidopsis* encodes four DCL enzymes (DCL1 – 4) that possess ribonuclease III activity. DCL1 processes dsRNA into 21 nt fragments, and is primarily responsible for processing microRNAs from their precursor RNAs encoded by the host. DCL1 also processes dsRNAs produced in the nucleus by DNA viruses, such as CaMV (e.g., 221). DCL3 processes dsRNA derived from heterochromatic regions of the genome or from DNA viruses into 24 nt fragments that direct methylation of homologous DNA sequences. DCL2 and DCL4 process dsRNA into 22 nt and 21 nt fragments, respectively, and these enzymes participate in antiviral silencing directed against plus-stranded RNA viruses. DCL4 functions in the primary role in this pathway, whereas DCL2 serves in an accessory role. Loss of function of both DCL2 and DCL4 is necessary to abrogate antiviral silencing. Interestingly, 24 nt vsRNAs generated by DCL3 accumulate during plus-strand RNA virus infection, but DCL3 alone is not sufficient for antiviral defense.¹⁰⁸ Antiviral silencing against plus-strand RNA viruses initiates when dsRNAs produced during replication, gene expression, or regions of duplex RNA secondary structure are cleaved by DCL2 and DCL4 to produce populations of 21 and 22 nt vsRNAs in the infected cells.

Deep sequencing revealed vsRNAs distributed across entire viral genomes. However, some regions of viral genomes are “hotspots” from which disproportionate numbers of vsRNAs are derived. These hotspots correlate with regions of secondary structure in the viral genomes.^{221,313} However the correlation is not perfect,²⁵³ leading to a hypothesis that template specificities of RdRps may be associated with some hotspots.

The *Arabidopsis* genome encodes 10 AGO proteins, of which AGO1, AGO2, and AGO7 have been implicated in antiviral silencing.^{133,148,224,254,289,349} AGO proteins function downstream of DCL proteins by using the sRNA products as guides to direct both endonucleolytic cleavage and translation inhibition of RNA species containing homologous sequences, as well as methylation of homologous DNA sequences.^{142,336} AGOs are the catalytic components of the RNA-induced silencing complexes (RISCs). AGO proteins incorporate one of the strands from the sRNAs generated by the DCL enzymes, whereas the other strand is degraded. The incorporated sRNA then serves as a guide to direct the RISC to targets containing complementary sequences including viral genomes and mRNAs.^{61,76,77,298,303} In most cases, the endonuclease activity in the piwi domain of AGO slices the target RNA of viral origin. Cleaved viral RNAs are degraded rapidly by cellular exonucleases. Therefore, RISC is programmable, adaptable, exquisitely specific, and serves as a second layer of antiviral RNA silencing defense.

RdRps provide plant cells with the ability to amplify vsRNAs, which is needed for effective antiviral silencing.²⁵³ In antiviral defense, RdRp levels increase during viral infection^{151,365} and direct synthesis of nascent double-stranded RNA (dsRNA) using templates of viral origin. These dsRNAs are then processed by the DCL enzymes to generate additional vsRNAs that can be bound by AGO1 to direct specific

degradation or modification of viral templates. The *Arabidopsis* genome encodes six RdRps, and of these, RDR1 and RDR6 function mainly in antiviral defense.^{108,252,253,350} *rdr1 rdr6* double mutants support systemic infections by mutant viruses that lack VSR activity such as CMVΔ2b and TuMV-AS9, which cannot infect wild-type plants.^{108,350} Current evidence indicates that RDR1 and RDR6 interact synergistically, because the *rdr1 rdr6* double mutant leads to much higher levels of CMVΔ2b genomic RNA than either single mutant.³⁵⁰ The activity of RDR1 is required for high levels of TuMV and CMV vsRNAs, because these are drastically reduced in *rdr1* mutants. However, *rdr1 rdr6* double mutants are much more susceptible to TuMV-AS9 or CMVΔ2b than the single mutants.^{108,350} The explanation for this is that RDR1 and RDR6 have only partially redundant functions, and they appear to have different biases in their template preferences. RDR1 is involved in producing vsRNAs derived from RNAs 1, 2, and 3 of the CMV genome, but RDR6 is biased toward production of vsRNAs from RNA 3 and the subgenomic RNA 4. In addition, RDR1 is biased toward production of vsRNAs from the 5′ ends of CMV RNAs, whereas RDR6 has a bias toward the 3′ end. These template preferences would be advantageous, for example, if a VSR suppressed RDR1 function, leaving the plant with a functional RDR6 to limit viral infection.

DNA viruses are also targets of antiviral RNA silencing pathways.^{61,76,77,260,298,303,334} vsRNAs corresponding to the pararetrovirus CaMV and geminiviruses such as Cabbage leaf curl virus (CaLCuV) are readily detectable in infected plants.^{26,52,220} The biogenesis of vsRNAs from CaMV involves all four DCLs, and the 21, 22, and 24 nt classes of vsRNAs are found in CaMV-infected plants.^{26,220} Interestingly, in *dcl1*, partial loss-of-function mutants, accumulation of all three size classes is reduced suggesting that DCL processing of CaMV transcripts is hierarchical and facilitated by DCL1. DCL1 produces CaMV vsRNAs by processing the highly base-paired stem-loop region of the 35S leader of CaMV to produce 21 nt vsRNAs, which may improve accessibility of this structure to the other DCLs. Geminivirus vsRNAs are also 21, 22, and 24 nt, but their biogenesis does not depend on DCL1. Accumulation of 21 nt vsRNAs from CaLCuV is abolished in *dcl4* loss-of-function mutants.²⁶ Secondary structures within the geminivirus transcripts as well as regions of overlapping complementarity between the 3′ termini of convergent transcripts provide dsRNA substrates on which DCL2 – DCL4 act.³³⁴ Although geminivirus transcripts are posttranscriptionally targeted, their DNA genomes are the target of transcriptional gene silencing (TGS). The 24 nt vsRNAs bound to AGO4 direct methylation of complementary viral DNA sequences cause TGS. AGO4 mutants are deficient in RNA-directed DNA methylation and as a result they are hypersusceptible to geminiviruses.²⁵⁹

Viral Suppressors of RNA Silencing (VSRs)

Although the innate plant defense systems are effective, it is clear that viruses have evolved diverse strategies to counteract plant defenses (see Fig. 72.31). The ability of a virus to suppress defenses in a particular host species or group of related species is one factor that enables systemic infection. The best-characterized counter defense deployed by viruses is suppression of RNA silencing by VSRs.^{44,61,76,77,298} VSRs are typically identified based on their ability to prevent the initiation of

RNA silencing or their disruption of the maintenance of established RNA silencing of marker genes such as GFP. Most RNA and DNA plant viruses encode at least one VSR with some viruses in the *Closteroviridae*, such as Citrus tristeza virus (Closterovirus) and Tomato chlorosis virus (Crinivirus), encoding as many as three VSRs.¹⁹⁶ An extensive list of VSRs of plant DNA and RNA viruses is provided in reference 61. In general, VSRs are not conserved in sequence across broad taxonomic boundaries, and they employ different strategies to interfere with the RNA silencing pathway. However, a few major themes have emerged for mechanisms of VSR function including (a) the targeting of silencing-related RNAs and (b) the interaction of VSRs with silencing-related host proteins.⁶¹ These mechanisms inhibit viral RNA sensing and dicing, prevent RISC assembly, or interfere with epigenetic modification of viral genomes.⁴⁴

TARGETING SILENCING-RELATED RNAs

Sequestration of vsRNAs is the most widely used mechanism for suppression of RNA silencing for three major reasons. The first is that vsRNA sequestration prevents assembly of functional RISC. Second, vsRNA sequestration can prevent the proper processing and maturation of vsRNAs. Finally, sequestration prevents vsRNA mobility that allows vsRNAs to move ahead of the virus to establish an antiviral state in cells neighboring infected cells. The best characterized example of a VSR that sequesters vsRNAs is the P19 protein of tombusviruses. P19 functions as a homodimer that binds to the 19-bp dsRNA region of small RNA duplexes in a sequence-independent fashion. X-ray crystallography of P19 bound to small RNA duplexes demonstrated that it is a molecular caliper that specifically measures and binds to small RNA duplexes that would be produced by the primary antiviral dicing enzyme DCL4^{335,369} (Fig. 72.32). This binding prevents virus-derived small RNAs from being loaded into RISC where they would direct cleavage of the viral RNAs from which they were derived. VSRs from at least 11 plant virus genera have been demonstrated to have the ability to bind sRNAs.⁶¹ Sequestration of vsRNAs has also been associated with inhibition of 2' O-methylation of sRNAs in the cases of tombusvirus p19, potyvirus HC-Pro, and Cr-TMV p122.^{60,84,195,342} Methylation by the HEN1 (HUA ENHANCER1) methyltransferase is necessary for the maturation of sRNAs, and thus, nonmethylated vsRNAs are expected to accumulate at reduced levels. A final interesting example

of targeting silencing-related RNAs is the RNase3 protein of Sweet potato chlorotic stunt virus. This protein has an RNase III activity that cleaves 21, 22, or 24 bp products of DCLs into 14-bp fragments that cannot function in RNA silencing.⁶²

INTERACTION OF VSRs WITH SILENCING-RELATED PROTEINS

AGO proteins are frequent targets of VSRs, through either direct or indirect interactions, and there is evidence that DCLs can be targets as well.^{68,125,208,209} The P0 protein of Potato leaf roll virus is essential for infection; it interacts with the PAZ domain and other nearby regions of AGO proteins. Through its F-box motif, P0 recruits SCF E3 ubiquitin ligase proteins, which promote the degradation of the bound AGO.^{19,30,241} The 2b protein of CMV strain Fny interacts with AGO1, and seems to directly inhibit its activity.³⁷⁶ It is important to note that the 2b protein of CMV strain TAV has been shown to bind sRNAs,²⁶⁶ suggesting that the 2b proteins of CMV strains can function by different mechanisms. The P1 protein of Sweet potato mottle virus (*Ipomovirus*) and the p38 coat protein of TCV represent another strategy for targeting AGO. These VSRs were both found to contain (glycine tryptophan) GW motifs that mediate binding to AGO proteins.^{15,117} Interestingly, the presence of GW motifs appears to represent a form of molecular mimicry, because host-encoded proteins containing GW motifs are involved in assembly of functional RISC. Inhibition of AGO1 by TCV p38 was further shown to disrupt DCL homeostasis: DCL1 becomes overexpressed leading to decreased expression of DCL3 and DCL4, which is the primary antiviral DCL in Arabidopsis.¹⁵

In addition to serving as the translational activator (TAV) for translation reinitiation, CaMV P6 is a VSR that directly targets vsRNA processing.^{125,194} When P6 enters the nucleus, it interacts with dsRNA-binding protein 4 (DRB4). DRB4 is required for DCL4 activity, so P6 causes loss of this key antiviral silencing factor. VSRs of geminiviruses interfere with epigenetic modification of their genomes,²⁶⁰ which is interesting because methylation of geminivirus genomes inhibits their replication.^{38,88} The AL2 and L2 proteins of the geminiviruses Tomato golden mosaic virus and Beet curly top virus, respectively, are VSRs that interfere with the methylation cycle in order to promote viral replication. These VSRs bind and inactivate adenosine kinase (ADK), which is needed for the efficient production of S-adenosyl methionine (SAM), the donor of methyl groups on DNA and histones⁴¹ (Fig. 72.33).

FIGURE 72.32. Stereo view of the structure of a co-crystal of P19 with a 21 nt small interfering RNA (siRNA) at 1.85 Å resolution. P19 forms a dimer indicated in magenta and purple. Note the alpha helices that serve as calipers by framing the ends of the RNA helix via tryptophan residues that stack with the terminal bases of the RNA. (From Ye K, Malinina L, Patel DJ. Recognition of small interfering RNA by a viral suppressor of RNA silencing. *Nature*. 2003;426:874–878, with permission.)

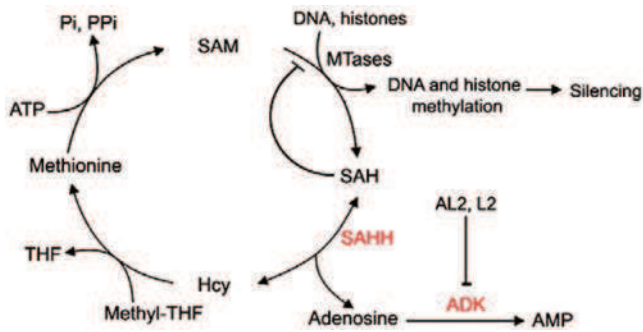

FIGURE 72.33. Inhibition of the methyl cycle by the AL2 and L2 viral suppressors of RNA (VSRs) of geminiviruses. (From Bujarski JJ, Dreher TW, Hall TC. Deletions in the 3'-terminal tRNA-like structure of brome mosaic virus RNA differentially affect aminoacylation and replication in vitro. *Proc Natl Acad Sci U S A* 1985;82:5636–5640, with permission.)

Although many VSRs may function autonomously, some VSRs require host factors for their silencing suppressor activity. The potyvirus VSR HC-Pro and TCV p38 were both shown to require an ethylene-inducible host transcription factor named RAV2.⁸⁶ Among the *Arabidopsis* genes found to be upregulated by RAV2 in the presence of HC-Pro were *FRY1* and *CML38*, two endogenous suppressors of RNA silencing. These results suggest that suppression of RNA silencing by HC-Pro could involve the upregulation of a set of host genes that antagonize antiviral silencing defenses. It has also been postulated that the geminivirus VSR AL2 induces the expression of host genes that negatively regulate RNA-silencing pathways.³²³ This function of AL2 is distinct from its role in inhibiting the methyl cycle and suggests that this protein promotes viral infection by interfering with different silencing pathways.

The ability of VSRs to interfere with host RNA-silencing systems has many detrimental effects upon hosts in addition to the promotion of virus infection. The presence of ectopically expressed VSRs in transgenic plants can phenocopy many of the symptoms of viral infections, and many VSRs were known previously to be pathogenicity determinants.³⁴³ Inhibition of DCL or AGO by VSRs can interfere with the biogenesis and function of endogenous siRNA species, such as miRNAs and trans-acting siRNAs (ta-siRNAs), which regulate many aspects of plant growth and development, as well as responses to the environment.²⁹⁸ Expression of three VSRs—HC-Pro, P19, and pecluvirus P15—causes misregulation of transcription factor AUXIN RESPONSE FACTOR 8 (ARF8).¹⁴⁹ *ARF8* expression is regulated posttranscriptionally by AGO1 via miR167 during the normal course of plant growth and development. Developmental defects in the transgenic plants were alleviated when an *arf8* loss-of-function mutation was introduced into the VSR-expressing lines demonstrating that misregulation of *ARF8* is responsible for symptom-like phenotypes induced by these VSRs. In addition, *arf8* mutants supported TuMV accumulation similar to wild-type plants, but they did not develop symptoms similar to wild-type plants. Therefore, virus accumulation can be uncoupled from symptoms, and misregulation of genes such as *ARF8* have apparently neutral effects on virus titer in experimentally inoculated plants. It is important to note, however, that VSRs do not account for all the symptoms observed

in systemically infected plants. For example, in this *ARF8* study, the authors noted that the *arf8* mutation did not alleviate chlorosis induced by TuMV. Furthermore, when *dcl2 dcl4* double mutants are infected by TuMV-AS9 carrying a mutation in HC-pro or by CMVΔ2b mutants that lack VSR activity, they still display stunted growth phenotypes.^{77,108} These observations provide strong evidence that viral factors other than VSRs also contribute to symptoms.¹⁸⁰

The discovery and intense study of antiviral silencing has led to some important technological advances that have aided plant research and control of viral diseases. The ability of viruses to trigger the RNA-silencing pathway has been exploited extensively for gene function analysis by the method of virus-induced gene silencing (VIGS).¹⁸ VIGS provides a way to transiently and specifically knock down the expression of host genes (Fig. 72.34). Recent studies suggest that it may also be possible to exploit VIGS to alter host gene expression in a heritable fashion.^{155,295} Plant viruses engineered as VIGS vectors by carrying inserts homologous to plant genes silence the homologous plant gene as systemic infection occurs.²⁵⁰ This happens because sRNAs corresponding to the plant gene are generated as the plant attempts to defend itself against the recombinant virus. These sRNA are incorporated into RISC where they direct cleavage of the recombinant viral RNA as well as the host mRNA corresponding to the homologous sequences in the virus. The antiviral RNA silencing pathway can also be primed to protect plants against nucleic acid-based invaders. The expression of inverted repeat constructs or artificial microRNAs corresponding to viral sequences can be used to effectively engineer resistance against plant viruses.³⁰³ Indeed studies investigating pathogen-derived resistance through generation of transgenic plants carrying portions of viral genomes provided early clues about the roles of RNA silencing pathways in eukaryotes.^{185–187}

FIGURE 72.34. Virus-induced gene silencing (VIGS) of *Phytoene desaturase* (PDS) in soybean. A Bean pod mottle virus vector carrying a 300-bp fragment of *PDS* was used to infect soybean plants. The soybean leaves appear white, because *PDS* is needed to produce carotenoid pigments that protect chloroplasts from photobleaching.

FUTURE PERSPECTIVES

Virus–Host Interactions

Although some molecular details of plant virus structure and replication are among the best characterized of all viruses, much remains to be learned, of course. We end by discussing a few areas of plant virus research that are moving rapidly and promise to open new vistas in our understanding of plant viruses. In general, the host side of the virus–host interaction is much more complex than the virus with its small genome and handful of proteins. For example, although cis-acting viral translational control signals are well studied, the interactions with host components and their effect on host translation in general are not well known. These host components include translation initiation factors,³¹⁹ translation elongation factors, ribosomal proteins,¹⁸² and regulatory kinases such as TOR and S6K1.^{288,367} The fact that host proteins involved with translation have been associated with viral replicases also implicates them in viral replication.^{183,366} More detailed understanding of these interactions will help to resolve the important problem of how viral RNAs are able to outcompete host mRNAs to successfully parasitize ribosomes for translation yet eventually serve as templates for viral replication.

Innate Immunity Signaling Pathways

Many details of host resistance mechanisms have been uncovered, but important outstanding questions remain. Antiviral silencing pathways are known, but the complexity of some of the gene families involved, such as the AGO family, allows for specialization and subfunctionalization of the participating proteins. Additional work is needed to firmly establish the functions of the various gene family members in antiviral silencing. As we move away from model organisms and into crop species that have much more complicated genomes, we may discover more interesting nuances in the functions of proteins involved in antiviral silencing. The many VSRs that have been identified offer critical reagents with which to dissect the antiviral silencing pathways.

The signaling pathways activated by viral resistance genes have been studied in great detail. However, we still lack a clear understanding of the biochemical details of recognition and early signaling events. The complexity of and our incomplete understanding of plant defense responses has also complicated efforts to understand the molecular basis for how a plant becomes resistant to a virus after defenses are activated by *R* genes. What specific response or group of responses that occur during hypersensitive cell death actually inhibit further viral infection? There are interesting links between *R* gene–mediated resistance and antiviral silencing that merit further exploration such as the induction of genes involved in RNA silencing⁴⁷ and the recent discovery that expression of the *N* gene encoding TMV resistance in tobacco is regulated by miRNAs.¹⁸¹

Plant Virus Cell Biology

The cell biology of viral processes in plants has long lagged behind that of animal viruses. However, rapid progress is being made in our understanding of the structure and localization of virus replication vesicles (replication factories), and in intracellular and intercellular trafficking of the viral genome from these replication factories to the plasmodesmata and into the neighboring cell.^{173,231} This has been achieved through electron microscopy and tomography to reconstruct three-dimensional images of the perinuclear endoplasmic reticulum, for example.⁶⁹ In addition,

the use of multiple fluorescent proteins fused to host proteins with known subcellular localization sites and bimolecular fluorescence complementation assays have enabled the interactions of host and viral proteins and their trafficking to be unveiled.^{32,353} These and other systems biology approaches to characterize entire virus–host protein interaction networks^{182,218,227} are becoming the norm for modern plant virology. With the application of these and other new techniques such as VIGS and next-generation sequencing, we are indeed—as noted by Karen-Beth Scholthof—“at the dawn of mechanistic plant virology studies”.²⁹⁰

Plant Virus Ecology

Finally, a completely different emerging field of research is the role of plant viruses in ecosystems.³⁶⁴ In this burgeoning research area centered on the effects of pathogens on wild (nonagricultural) ecosystems, plant viruses serve as model organisms.^{202,248} In particular, several ecology laboratories are investigating the role of BYDV and CYDV in the “battle” between perennial native grasses and invading annuals. It appears that wild oats (weeds) imported from Europe have taken over the grasslands of California in part by their ability to accumulate virus, transmit it to the native perennials (via aphids), and then shed the virus by dying in the winter, leaving virus-free seed to sprout each spring. The uninfected progeny oats then outcompete the native perennials, which remain infected from year to year, reducing growth rate, and rendering them less fit.^{29,201}

The advent of next-generation sequencing has revolutionized plant virus ecology by allowing massively parallel, high-throughput genome sequencing of all viruses in an entire ecosystem.²⁷⁹ These “ecogenomics” techniques have revealed plant virus populations in Costa Rican forests spanning a wide range of ecosystems,^{279,364} and in native tall grass prairies in the central United States.²⁸⁷ As these environmental virus sequencing projects continue, it is likely that the next few years will see a many-fold increase in the number of known plant viruses.

EPILOGUE

The authors realize that many viruses and major areas of plant virology were not included in this review, as this chapter was not intended to be a comprehensive summary of all plant virology. Our intent has been to provide representative examples of plant viruses and plant viral functions. We hope that the reader has come away with an understanding of plant virus genome structure and function, and vector and host interactions that provides insight on viral mechanisms in general, including those relevant to research on vertebrate viruses. Moreover, this review is intended to spotlight major differences between plant and animal viruses, owing to the fundamental differences between plant and animals, and to celebrate the diversity of life at all levels including that of the virus.

IMPACT OF INSECT VIRUSES

Insects comprise well over half of the existing animals on earth. They include an estimated six to ten million species and represent some of the most diverse and successful animals on the planet. Accordingly, the RNA and DNA viruses infecting insects are also highly diverse. It is likely that these viral pathogens have existed as long as the insects themselves. They therefore have evolved along with their hosts for more than 350 million years. Insect viruses inflict disease and mortality in their hosts. Certain insect viruses are also serious pathogens of vertebrate animals, humans included. Thus, the insect viruses have long been of medical concern, agricultural relevance, and scientific interest to humankind. Indeed, much of the early research on insect viruses focused on their impact on human health and their applied use in insect control strategies. As molecular studies of insect viruses advanced, it was quickly appreciated that these viruses provide important tools for investigating fundamental problems in molecular and cellular biology and have direct application to the field of biotechnology.

Molecular and Cell Biology, Virus Interactions, and Virus Evolution

Biochemical and genetic studies on the multiplication and host pathogenesis by insect viruses have contributed enormously to our understanding of molecular and cellular biology, virus structure and assembly, virus–host interactions, and disease states.

These advances are due in a large part to the diversity of insect viruses as well as the availability and convenience of cell cultures or live insects in which to propagate them. Such systems, when combined with the ease with which insect viruses can be engineered or genetically manipulated, provide remarkably high yields of virus particles or virus-encoded macromolecules for studies of gene structure and function. There are also distinct experimental advantages to the use of many insect hosts, including their relatively simple genomes that have been sequenced and annotated. Compared to vertebrates, insects exhibit limited genetic redundancy, a property that has simplified studies on host–virus interaction pathways. Finally, there exists a striking conservation of genes and genetic pathways between insects and mammals. Thus, discoveries with insects and their viruses have led to important insights for all animals, humans included. In a striking example, the identification of inhibitor-of-apoptosis (IAP) genes in the insect baculoviruses led to the discovery of IAP homologs in mammals and subsequently established the critical role of IAPs in cell survival, normal development, virus pathogenesis, and human diseases that include cancer and neurodegeneration (reviewed by 186,235,280,298,326). The baculoviruses encode other suppressors of apoptosis that have revealed novel mechanisms for the regulation of apoptosis and have provided important insight into the role of apoptosis in insects and mammals (see later discussion).⁵⁶

There are numerous examples by which insect viruses have advanced fundamentals of biology. The insect cypoviruses of *Reoviridae* were the first to reveal the critical 7-methyl GpppN cap structure on eukaryotic mRNAs.¹⁰² Cricket paralysis virus of the family *Dicistroviridae* has provided insight into the function and structure of internal ribosomal entry sites and novel mechanisms for initiation of protein synthesis.¹⁴⁴ The nodaviruses revealed the first example of an animal virus–encoded suppressor of host RNA silencing (also known as RNA interference [RNAi]).¹⁹⁶ Other novel RNAi suppressors have recently been identified in the dicistroviruses. Finally, the polydnaviruses have disclosed a remarkable symbiotic relationship between virus and host that involves virus-mediated immune suppression.^{20,302,345} Recent polydnavirus discoveries are reworking the definition of a virus. Insect viruses have collectively provided key understanding in numerous aspects of cell biology, host–virus interactions, and pathogenesis.

Insect viruses have also provided unique insight into virus evolution. Due to the close association of insects with plants and other animals, natural exchange and mixing of viruses is accelerated. Insect viruses within the families *Poxviridae*, *Rhabdoviridae*, *Reoviridae*, *Picornaviridae*, and *Parvoviridae* have vertebrate counterparts, leading to speculation that viruses of higher animals arose from insect virus ancestors. Certain insect

viruses have co-evolved with unrelated insect virus families. The striking conservation of specific genes among diverse insect virus families—including baculoviruses, entomopoxviruses, orthomyxoviruses, ascoviruses, and iridoviruses, as well as the newly discovered relationship between polydnaviruses and nudiviruses—is consistent with co-evolution of invertebrate viruses. Certain DNA viruses of insects also accommodate host-derived transposons and retroid elements, which are especially abundant in arthropods. Stable retention of such mobile genetic elements facilitates virus evolution and likely contributes to the exchange of genes between a virus and its host organism.²⁷⁸

This chapter describes those viruses that multiply primarily or exclusively in insects: baculoviruses, polydnaviruses, ascoviruses, nudiviruses, nodaviruses, tetraviruses, and the dicistroviruses. Viruses such as the arboviruses, in which insects are used as temporary hosts or vectors during transmission, are described in other chapters. Insect virus families such as the entomopoxviruses, iridescent viruses, densoviruses, and cypoviruses have been described elsewhere.^{4,220}

Expression Vectors for Foreign Genes

Among eukaryotic viruses, the insect viruses are among the best known for their use as vectors for foreign gene expression because of their productivity, efficiency, and utility. The most widely used vectors are those derived from the helper-independent baculoviruses (reviewed by 49,159,167,175,260,321). This widespread application for these large DNA insect viruses is the direct result of intense molecular studies on their genetics, biochemistry, and multiplication strategies; it represents a striking example of the utility of insect viruses for basic and applied research. The remarkable strength of very late baculoviral promoters, the high level of virus multiplication, the extraordinary capacity for protein synthesis in cultured insect cells, and the ability to maintain large foreign DNA inserts are the principle factors that contribute to the efficiency and popularity of baculoviruses as eukaryotic expression vectors. The most used baculovirus expression vector system is derived from *Autographa californica* multicapsid nucleopolyhedrovirus (AcMNPV), a nuclear-replicating DNA virus that can generate virus-specific macromolecules comprising well over one-third of the mass of the infected cell. Thousands of different heterologous proteins have been expressed and subsequently studied by using the AcMNPV system since its original development in the early 1980s by the independent laboratories of Max Summers and Lois Miller.^{258,294}

Baculovirus vectors have been improved significantly for speed of recombinant virus generation, purification, and production of a large variety of protein types, including cytoplasmic, nuclear, secreted, and membrane-bound polypeptides (in order of abundance). Methods for recombinant vector production are now efficient and routine. Strategies for insertion and simultaneous expression of multiple genes or for temporally regulated, promoter-specific expression are available. Since post-translational modifications and biological activity of the resulting protein products often mimic or parallel that of mammalian cells, these vectors have provided abundant material for applications in diagnostics, therapeutics, and vaccine development, as well as general studies on protein structure and function. Like other expression systems, however, baculovirus vectors have advantages and disadvantages that depend on the type of protein to be produced.^{159,321} Insect cell lines have also been improved

by adaptation to serum-free media and specific engineering for glycosylation of protein products that mimics that of mammalian cells.¹⁵⁹ Live insect larvae have also been used as effective and convenient large-scale bioreactors for the production of high levels of many important proteins for academic and commercial purposes. *Bombyx mori* nucleopolyhedrovirus (BmNPV) has been used as an efficient vector for protein production in silkworms (reviewed in 167). For antigen preparation, the baculoviruses have also been used to express heterologous peptides, usually as fusions in their surface envelope.^{175,260,321}

The promoters for certain immediate early baculovirus genes are highly active in the absence of virus proteins.^{178,181,267,313} As a result, several of these baculovirus promoters, including those for IE1 and IE2, have been used extensively for high-level gene expression in diverse lepidopteran and dipteran insects by transient transfections or the generation of stable cell lines.⁷⁸ This approach allows long term, high-level expression in the absence of virus vectors.

It is noteworthy that other insect viruses, including the entomopoxviruses,²⁵⁹ densoviruses, and alphaviruses, have also been exploited as expression vectors. Likewise, flock house virus of the RNA virus family *Nodaviridae* has been used to express foreign epitopes on the surface of its isometric virion particle (reviewed by 327).

Gene Transduction, Delivery, and Gene Therapy

As a result of recent advances, the baculovirus AcMNPV has been used effectively as a gene transfer vector for a surprising variety of vertebrate cells, including those from mammals (reviewed by 49,339). Although baculoviruses can enter mammalian cells, they do not multiply or cause widespread cell death. Thus, when inserted into the baculovirus genome under control of appropriate mammalian transcriptional signals (promoters and enhancers), foreign genes are readily transduced and expressed after inoculation of mammalian cell lines. Expression is transient and levels vary depending on the protein. Interestingly, early AcMNPV genes are expressed, including the immediate early proteins IE1 and IE2 (see later discussion) and those viral genes that respond to these potent transcriptional activators.⁴⁹ The mechanism of virus entry is unknown, likely differing for each mammalian cell or tissue type. Nonetheless, the AcMNPV envelope fusion protein GP64 (see later discussion) is required. GP64 has been used to facilitate entry of pseudotyped envelope viruses into mammalian cells.^{124,246,292}

Because of its lack of multiplication in mammalian cells, its low cytotoxicity, the capacity for foreign gene expression, and its high transduction efficiency, AcMNPV has also been evaluated as a gene therapy vector. Applications have included its use in cancer therapy, regenerative medicine, vaccine vectors, and gene product ablation by RNA interference.^{49,339} Only preclinical trials have been conducted to date. In the case of baculovirus-mediated cancer therapeutics, tested approaches include virus-mediated expression of tumor-specific antigens for anticancer vaccines, introduction of functional tumor suppressors (e.g., P53) or proapoptotic genes, and the delivery and expression of suicide genes that confer tumor-specific susceptibility to select toxins or chemotherapeutic drugs. It is expected that these novel therapeutic approaches that exploit insect viruses will receive more attention in the future. AcMNPV vectors have already found use in the production of adenovirus gene therapy reagents.²⁹⁵

Biopesticide Viruses for Insect Control

While comprising over 80% of the existing animal species on earth, many insects present serious biomedical adversity for humans and cause significant agricultural and forest damage on a worldwide scale. Thus, it is not surprising that throughout history humankind has sought to control insects. In nature, insect populations are held in balance by predation, parasitism, and infection by microbial pathogens of viral and fungal origin. Of these diverse factors, viruses have numerous practical advantages for deployment as insect control agents and already represent viable components in current integrated pest management strategies.^{44,305}

In nature, viruses cause widespread epizootics and morbidity in insects, especially within dense populations. Spontaneous epizootics by viruses have occurred frequently in agricultural and forest settings (reviewed by 277). Nonetheless, dependence on epizootics for insect control has been impractical due to the unacceptable levels of crop damage that occur before the pest population declines. Thus, much effort has been invested in the development of viral biopesticides for field application in agriculture. Several viruses have already been used as effective, safe, and highly specific biocontrol agents that have the added benefit of reducing dependence on broad-range, toxic chemical insecticides. Of these viruses, the DNA baculoviruses have received the most attention due to their relative safety in the environment, their insect-specific virulence, the capacity for large-scale production, and the availability of effective formulations for application in agricultural and forest settings.

In one of the most successful applications of viral pesticides, the baculovirus AgMNPV is currently used to control the soybean looper on a large scale in Brazil.^{156,225,305} Other baculoviruses are used in Europe to control the codling moth, a common pest of fruit crops. In 1975, the Environmental Protection Agency registered the first baculovirus as an insecticide in the United States. While other baculoviruses have also been registered, their implementation has been pursued mostly by US agencies.^{25,225} Commercial development of virus insecticides has been sporadic due in part to restricted markets and limitations in their efficacy. Nonetheless, because the baculoviruses are amenable to genetic engineering, progress has been made to improve insecticidal efficacy by the insertion of insect-specific toxin or hormone genes.^{156,305} Carefully controlled field tests of genetically improved baculoviruses have been conducted in several countries, including the United States and United Kingdom.^{31,156,225} It is expected that viral insecticides will have an expanded role in integrated pest management programs as insects acquire resistance to chemical pesticides and environmental concerns increase. This practical application should expand with continued discovery and characterization of other virus families (ascoviruses, iridoviruses, tetraviruses, entomopoxviruses, nodaviruses, dicistroviruses, and cytopoviruses) that are potent pathogens of insects.

CLASSIFICATION OF INSECT VIRUSES

Insects are susceptible to highly diverse families of DNA and RNA viruses (Table 73.1). While some viruses are unique to arthropods, many members of insect virus families have counterparts among vertebrate viruses. Interestingly, insect-specific viruses also have novel properties that are common among insect virus families. A striking example is the use of an occluded virus particle for virus transmission between insect

hosts. This morphologic feature is conserved among diverse virus families, including the baculoviruses, entomopoxviruses, cytopoviruses (reoviridae), and possibly the nudiviruses.

DESCRIPTION OF INSECT VIRUS FAMILIES

Baculoviridae

Classification of Baculoviruses

Members of the family *Baculoviridae* have a large, circular genome of double-stranded DNA (dsDNA) that is packaged into an enveloped, rod-shaped virion.³¹¹ The family name is derived from the Latin term “baculum,” meaning stick or staff, to describe the shape of the virion. These viruses are characterized by their two morphologically distinct forms of infectious particles: occluded virus (OV), comprised of enveloped virions embedded within a crystalline matrix of protein; and budded virus (BV), comprised of a single virion enveloped by a plasma-derived membrane. The family consists of four genera. The alphabaculoviruses and betabaculoviruses infect lepidopteran insects (moths and butterflies), whereas the gammabaculoviruses and deltabaculoviruses infect hymenopteran insects (wasps and sawflies) and dipteran insects (mosquitoes), respectively (reviewed in 277). The alpha- and betabaculoviruses include the nucleopolyhedroviruses (NPVs) and granuloviruses (GV), respectively; these two virus groups are the best characterized of *Baculoviridae*. For GVs, a single virion is embedded within large ovoid cylindrical-shaped OV particles, which collectively appear as “granules” under light microscopy. By contrast, the polyhedral-shaped OV particle (polyhedra) of the NPVs has numerous (>20) virions. The OV are produced and accumulate in the nucleus of NPV-infected cells, whereas in GV-infected cells, intracellular OV assemble after the nuclear membrane disintegrates.

Baculoviruses infect well over 500 different species of insects. To date, virus isolates have only been identified in arthropods, mostly from insects of the order Lepidoptera. The NPV type species is *Autographa californica* multicapsid nucleopolyhedrovirus (AcMNPV), which was isolated originally from and named after the alfalfa looper *Autographa californica*. The GV type species is *Cydia pomonella* granulovirus (CpGV), isolated from the codling moth *Cydia pomonella*. Baculoviruses usually have distinct and relatively narrow host ranges that are limited to insects within a single genus or family. However, some baculoviruses, such as AcMNPV, have broad host ranges that include >40 lepidopteran species.

In the next sections, the molecular biology and biochemical mechanisms of baculovirus multiplication are described, comparing these unique viruses to the DNA viruses of vertebrates and highlighting the properties of baculoviruses that have been exploited for important applications in biotechnology. Recent reviews describe additional details of baculovirus biology, host and cellular interactions, evolution, host range, pathology, and vector applications.^{29,49,57,61,63,134,141,156,159,175,250,260,277,316,321}

Baculovirus Structure: OV and BV

Baculoviruses have a biphasic multiplication cycle in which BV is produced before OV (reviewed by 277). Both virus forms (Fig. 73.1) are infectious and contain one or more rod-shaped nucleocapsids (30–60 nm in diameter, 250–300 nm long). The nucleocapsid contains a single covalently closed circle of double-stranded genomic DNA that is associated with a 6.9-kDa, protamine-like core protein.³³⁷ The outside proteins of the

dsDNA, double-stranded DNA; ssDNA, single-stranded DNA; dsRNA, double-stranded RNA; ssRNA, single-stranded RNA.

^a*Heliothis zea* virus 1 and *Oryctes rhinoceros* virus (nudiviruses) were previously classified as members of Baculoviridae but were revised by the International Committee on Taxonomy of Viruses (ICTV) to "unclassified".

nucleocapsid interact to form ring-like subunits stacked every 4.5 nm; these include one major ~40-kDa capsid protein plus additional minor proteins.³³⁸ The apical end of the virion has a distinct structure consisting of several unique proteins, suggesting a specialized function.³²⁸ One of these virion end-structure proteins is pp78/83, a Wiskott-Aldrich syndrome (WASP)-like protein that facilitates nuclear actin assembly and is essential for production of progeny virus.¹⁰⁸

An especially distinctive feature of the baculoviruses is the large size (0.15–15 μ m diameter) and polyhedral or oval shape of their OV particles (Fig. 73.1). The OV mediates virus transmission between insect larvae, which is the developmental stage most susceptible to baculovirus infection. Upon inges-

tion, the OV protein matrix dissolves in the alkaline pH of the larva's midgut to release the occlusion-derived virions (ODV) that initiate infection of the midgut epithelium. The crystalline matrix of the OV is comprised primarily of a single ~29-kDa protein, designated either polyhedrin or granulins for the NPVs and GVs, respectively; these two proteins are closely related. The ODV of NPVs (Figs. 73.1A and 73.1B) are embedded in the matrix either as single nucleocapsids (SNPVs) or multiple nucleocapsids (MNPVs) that are surrounded by a single membrane envelope. This nuclear-derived envelope contains virus-encoded proteins that are responsible for binding to midgut epithelial cells, the initial site of infection.²⁷⁷ The membrane envelope is synthesized *de novo* or represents a modified form

FIGURE 73.1. Nucleopolyhedrovirus OV and BV particles. **A:** Cross-section of an OV particle from a single-capsid NPV (SNPV). Single nucleocapsids (NC) are enveloped within a unit membrane (E) and embedded within a matrix of polyhedrin protein (P). The carbohydrate-rich calyx (C) covers the external surface of the particle, which is ~2 to 3 μm in diameter. **B:** Cross-section of an OV particle from a multi-capsid NPV (MNPV). The membrane envelopes (E) contain multiple nucleocapsids and are embedded within the polyhedrin matrix (P) of the particle. **C:** Budded virus (BV) particle during budding. The BV contains a single nucleocapsid (NC) (~30 \times 250 nm) surrounded by a virus glycoprotein-containing envelope derived from the plasma membrane of the NPV-infected cell. **D:** Thin section of a typical cell in the late phase of MNPV infection. The virogenic stroma (VS) and associated nucleocapsids (NC) are generated within the infected nucleus still contained by the nuclear membrane (NM). **E:** Enlarged thin section of an MNPV-infected cell nucleus early during the very late, occlusion-specific phase. Newly assembled nucleocapsids (NC) associate with intranuclear membranes, are enveloped (E), and embedded within the polyhedrin matrix (P). (Electron micrographs courtesy of Dr. Malcolm J. Fraser, Jr., University of Notre Dame.)

of the nuclear membrane.³⁵ On their surface, the mature OV particle has an additional covering of protein and carbohydrate known as the polyhedron envelope, or calyx.

The BV form is produced prior to OV during infection. BV is responsible for cell-to-cell transmission within the infected insect. It is the infectious particle for inoculating cultured cells, thus is the form used for baculovirus vectors. The BV consists of a nucleocapsid surrounded by a loose-fitting membrane envelope that is acquired by budding from the plasma membrane of the host cell (Fig. 73.1C); it is therefore distinct from nucleocapsids embedded within OV. The envelope fusion protein (EFP) is the most abundant viral protein associated with the BV membrane. The NPVs are subdivided on their EFP type (reviewed by 277). The EFP of group I NPVs (i.e., AcMNPV, OpMNPV) is GP64, whereas the group II NPVs (i.e., LdMNPV, SeMNPV) contain an F protein. GP64 is the best characterized of the baculovirus EFPs. It is a class III transmembrane glycoprotein that is required for efficient virus budding and BV

infectivity.²²³ BV can be neutralized by GP64-specific antiserum.^{330,363} GP64 likely interacts with the host-cell receptor or membrane components (which are still undefined in insects) and mediates membrane fusion upon activation by low pH in the endosome. Prefusion cleavage is not required. Detailed molecular studies^{199,200,363} and the postfusion crystal structure¹⁶³ have revealed that GP64 is a stalk-like, cross-linked trimer with an internal peptide domain required for fusion. However, the exact mechanism of GP64-mediated membrane fusion remains unclear. Because GP64 is essential for virus entry of mammalian cells during baculovirus-mediated gene transduction and is used to facilitate entry of a broad range of enveloped viruses into mammalian cells by using pseudotype strategies,^{49,124,246,292} protein GP64 represents an active area of research.

Baculovirus Genome Structure

The baculovirus genome is a large (80–180 kbp) covalently closed, supercoiled circle of dsDNA. To date, the complete

nucleotide sequence of >50 baculoviruses, including viruses from each genus, has been reported. This abundance of genetic information has provided important clues regarding baculovirus functions, evolution, and host interactions.^{138,141} About 30 genes have been identified as core genes that are shared by all baculoviruses and confer the distinctiveness to this unique family of insect viruses (reviewed by 134,140,141,277,315). Certain conserved genes are essential for baculovirus transcription (early and late phases), viral DNA synthesis, viral DNA packaging, and assembly of the OV and BV particles. Other core genes contribute specifically to baculovirus host range and the virus's unique life cycle within the insects. Not surprisingly, some of these genes are nonessential and thus dispensable for virus multiplication in cell culture.

AcMNPV is the best-studied baculovirus. Its 134-kbp DNA genome consists almost entirely of unique sequences that encode ~150 open reading frames (ORFs).^{6,277} The ORFs are closely spaced on both DNA strands with no apparent organization with respect to temporal expression. Early, late, and very late genes are interspersed throughout the genome. Most ORFs are separated by only 2 to 200 nucleotides. These intergenic regions have a high adenosine/thymidine content and function as promoter or termination sequences. In addition, the translational termination codon (usually UAA) often overlaps the polyadenylation signal, AAUAAA. Multiple examples of overlapping ORFs exist. Interestingly, there are few introns in baculovirus genomes. A rare example of splicing involves the nonessential *ie-0* gene and yields protein IE0 (see later discussion), which is nearly identical to transcriptional activator IE1.⁵²

AcMNPV RNA transcripts often initiate from within or extend through adjacent genes, a phenomenon especially prevalent among viral RNAs late in infection.^{95,177,208} Thus, numerous genes are transcribed into bi- or multi-cistronic RNAs wherein only the upstream ORF is preferentially translated. The biologic implication of this arrangement is unknown. There are also multiple examples of the transcription of overlapping and in some cases, antisense RNAs. Thus, the interspersion of temporal classes of RNA transcripts may have functional or regulatory significance. For example, activation of the very late promoter of *polh*, the gene encoding the major structural protein (polyhedrin) of OV, downregulates overlapping, antisense RNAs initiated downstream of *polh*.²⁴⁴

A distinguishing feature of the baculovirus genome is the presence of multiple copies of interspersed repetitive sequences ranging in size from 30 bp to 800 bp that are designated homologous regions or *hrs*.^{62,117} The *hrs* act as transcriptional enhancers^{117,121} and probably function as origins of viral DNA replication.^{171,254} AcMNPV contains eight *hrs*, which account for 3% to 4% of the genome. The *hrs* have a complex modular organization consisting of ~60-bp repeats, each with a highly conserved 28-bp imperfect palindrome (28-*mer*). The 28-*mer* is the minimal sequence required for orientation- and position-independent enhancement of promoter activity and DNA replication.^{192,274} The *hrs* bind host- and virus-specific proteins. In particular, the transcriptional activator IE1 binds as a dimer to the palindromic 28-*mer* in an interaction that is required for IE1-mediated stimulation of enhancer activity.^{176,192,275} Deletion of a single *hr* (either *hr1*, *hr1a*, *hr2*, *hr3*, *hr4a*, *hr4b*, or *hr5*) from the AcMNPV genome reduces transcription of proximal genes, but has no significant effect on viral DNA replication or virus multiplication.^{41,274} Thus, individual *hrs* are dispensable

and no single region is absolutely required for virus multiplication in cell culture. The functional significance of multiple origin elements remains unclear. Nonetheless, the novel distribution and repetition of the *hrs* or *hr*-like elements within multiple baculoviruses suggest that these sequences play a critical role in the virus life cycle.

Stages of Baculovirus Replication

PRIMARY AND SECONDARY INFECTION

Baculovirus multiplication in the insect larva is divided into primary and secondary stages to describe the initial infection of larval midgut cells and the subsequent infection of secondary tissues, respectively (Fig. 73.2). Although virus binding to the host cell initiates infection in both stages, aspects of primary and secondary infections differ. Secondary infection in the larva most closely resembles that of cultured cells. Most of the details of AcMNPV replication (see later discussion) have been obtained through studies of high-multiplicity infection of cultured SF21 (or clonal SF9) cells, a convenient cell line derived from the nocturnal moth *Spodoptera frugiperda* (Lepidoptera; noctuidae). It should be appreciated that the timing of replication events often varies between viruses and insect hosts.

ATTACHMENT, ENDOCYTOSIS, AND UNCOATING

Budded virus (BV) of AcMNPV enters the host cell (Fig. 73.2) by what appears to be receptor-mediated endocytosis (reviewed by 277). The specific host-cell receptor(s) or lipid molecules are unknown. The major glycoprotein of BV, EFP GP64 (see earlier discussion) is required for receptor interaction and envelope fusion of the endosomal membrane. After release within the cytoplasm, nucleocapsids migrate to the nucleus in a process that coincides with virus-induced actin polymerization.^{47,108} Nucleocapsids interact end-on with the nuclear pore, enter the nucleus, and uncoat their genome. Phosphorylation of the 6.9K protamine-like core protein by a virus-encapsidated protein kinase promotes DNA release.^{337,350} These processes are rapid since new viral RNA transcripts can be detected within 15 min after inoculation.^{52,122,152,180,230,312}

EARLY PHASE REPLICATION

By definition, the early replication phase precedes virus DNA replication. During this period that extends to 6 hours, baculoviruses express genes encoding transcriptional activators, a virus-specific RNA polymerase activity, DNA replication factors, apoptotic suppressors, and other critical factors. These early gene products prepare the cell for the enormous burden imposed by the synthesis of viral nucleic acid and structural components that can constitute more than a third of the cell's mass (Fig. 73.3A). The level and timing of early and late gene expression is orchestrated to insure proper temporal assembly of infectious BV and OV. Early viral gene products also block cell-cycle progression, causing infected cells to accumulate in S and G₂/M phases.^{34,155} In addition, filamentous actin and microtubules are redistributed, causing a dramatic rearrangement of the host-cell cytoskeleton that is manifested by nuclear hypertrophy and cell rounding. These changes are characteristic of the early stages of baculovirus infection.^{47,108,279}

Baculovirus gene expression involves a highly coordinated cascade of gene activation events that is regulated primarily at the level of transcription (reviewed by 94,277). Transcription of strictly defined early genes usually peaks between 6 and 12 hours

FIGURE 73.2. Baculovirus multiplication cycle. Except for the virus particle and the route of its entry, most steps in the baculovirus infection cycle are identical for an insect midgut epithelial cell (primary infection) or a subsequently infected nonmidgut cell (secondary infection). The steps for BV infection of a permissive cultured cell are the same as that for a secondary infection. Upon infection of a midgut cell by OV (top), the polyhedrin matrix of larval-ingested OV dissolves in the midgut lumen to release occlusion-derived virions that cross the peritrophic membrane and gain access to the columnar epithelial cells. These enveloped virions fuse with the microvilli membranes, releasing nucleocapsids into the cytoplasm for nuclear entry or transport to the basal membrane side of the midgut cell for budding into the hemocoel or tracheal epithelium. In secondary infections (right), enveloped BV in the infected larva's hemolymph or growth medium from infected cell culture attaches to unidentified cell-surface receptors and enters by endocytosis. As the endosome acidifies, the viral and endosomal envelopes fuse to release nucleocapsids into the cytoplasm. Occlusion-derived or BV-derived nucleocapsids both proceed to the nucleus, where they interact with the nuclear pore. The viral DNA genome is released by uncoating and the early phase of transcription and gene expression begins. Once the appropriate early gene products appear, viral DNA is synthesized in association with the newly formed virogenic stroma. Late gene expression occurs after DNA replication and produces structural components for the nucleocapsid, which then package just-replicated viral genomic DNA. During this late phase, newly assembled nucleocapsids exit the nucleus, migrate to the plasma membrane, associate with an envelope fusion protein, and exit the cell by budding to yield infectious BV. By contrast, during the very late phase, nucleocapsids are retained in the nucleus, acquire a nuclear-derived envelope, and become embedded within a crystalline matrix of polyhedrin to yield OV particles. Mature OV are released by virus-mediated cell lysis. (Drs. Nadine Dalrymple and David Taggart, University of Wisconsin-Madison, contributed to this illustration.)

after infection and declines thereafter as late viral transcription accelerates. During this early time, at least a portion of the incoming viral DNA genome adopts a nucleosome-like structure.³⁵¹ Early viral transcription is mediated by the host's RNA pol II.^{26,115,146,153,267} Early promoters resemble host RNA pol II promoters, complete with a consensus TATA element located ~30 bp upstream from the RNA start site.^{27,71,119,179,203,267,312} A tetranucleotide CAGT motif positioned at the RNA start site

is common to many early promoters and functions as a transcriptional initiator element.^{26,268} These core promoter elements also cooperate with upstream activating elements or more distal transcription enhancers (including the *hrs*) to interact with sequence-specific transcription activators. The *cis*-acting transcriptional control elements for multiple AcMNPV early genes have been defined, including those for *ie-1*, *gp64* EFP, *pp31*, *he65*, *p143*, and *p35*. Many early promoters are highly

responsive to virus-encoded transactivators, especially the multifunctional protein IE1 (see later discussion). As expected, host factors also participate in early transcription events.^{106,168,179,272} Remarkably, purified viral genomic DNA devoid of protein is infectious. Thus, host factors are sufficient to initiate infection, albeit at a rate slower than that of infectious virus particles. This feature is exploited in the generation of the baculovirus expression vectors.^{159,321}

Immediate early protein IE1 is the principal early trans-regulator of many baculoviruses. This nuclear phosphoprotein is highly conserved among the lepidopteran baculoviruses and is essential for virus multiplication by virtue of its transcriptional and DNA replication activities.^{253,286,300,307} IE1 transactivates early baculovirus promoters and contributes to a critical but unknown virus DNA replication function.^{27,119,120,178,182,203,230,252,253,273,307,312} Typical of transcriptional activators of DNA viruses, IE1 has a modular structure (Fig. 73.4). The N-terminal third consists of a potent transactivation domain that is largely acidic.^{176,276,293} A small stretch of residues at the extreme N terminus of IE1 is required for viral DNA replication.^{253,307} Furthermore, this N-terminal replication domain contributes to IE1 phosphorylation. Potential phosphorylation sites within a highly conserved cdc/cyclin B kinase-like motif (TPXR/H) within the replication domain are required for viral DNA replication and virus multiplication but not transactivation.³⁰⁷ Thus, phosphorylation may serve as a molecular switch to ensure proper division of IE1's DNA replication and transcriptional duties in a temporally controlled manner. The responsible kinase, either viral or host, is unknown. Also within its transactivation domain (Fig. 73.4), *AcMNPV* IE1 contains a highly conserved patch of basic residues (designated basic domain I) that is required for DNA binding.²⁴² This function of IE1 is essential for virus multiplication.³⁰⁶ IE1 binds as a dimer to the repetitive 28-bp palindromes that constitute the *hrrs*; IE1 binding is required for optimal transcriptional

FIGURE 73.3. Fates of baculovirus-infected cells. **A:** Wild-type *AcMNPV* infection of *Spodoptera frugiperda* SF21 cells. Upon successful inhibition of apoptosis by viral P35, the highly refractile OV particles (arrow) accumulate in the hypertrophied nucleus of each cell by 48 hours after infection. **B:** Late stages of apoptosis triggered by an *AcMNPV* *p35*-deletion mutant. When virus-induced apoptosis is not suppressed, SF21 cells undergo widespread apoptosis that includes the formation of membrane-enveloped apoptotic bodies (arrow). Magnification, 200 \times . (Micrographs courtesy of Gulam Manji, University of Wisconsin—Madison.)

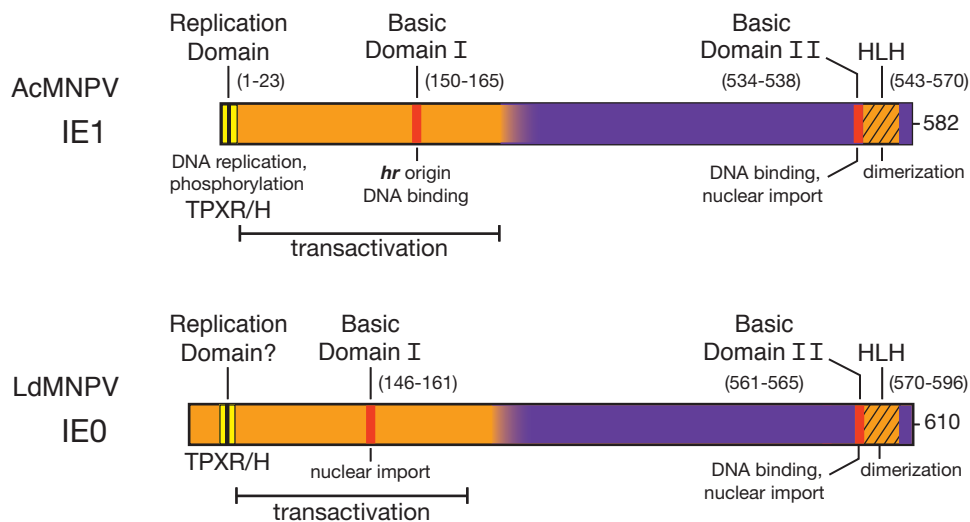

FIGURE 73.4. Structure of baculovirus transactivator IE1. NPV immediate early IE1 is a potent transcriptional activator essential for virus gene expression, DNA replication, and virus propagation. It has a conserved modular organization consisting of an N-terminal transactivation domain and a C-terminal helix-loop-helix (HLH) domain required for dimerization and nuclear import. The small basic domains (I or II) are required for DNA binding. IE1 from *AcMNPV* and *LdMNPV* share structural organizations but have very divergent sequences. Both possess N-terminal TPXR/H motifs required for DNA replication and phosphorylation³⁰⁷ but differ with respect to the function of their basic domains⁶⁸; *AcMNPV* basic domain I is required for *hr* DNA binding; the same domain in *LdMNPV* IE1 is required for nuclear import.

enhancer function of the *hrs*.^{117,121,176,192,230,274,275} The IE1 C terminus possesses a domain that also contributes to DNA binding (Fig. 73.4). Here, IE1 contains an oligomerization domain and a novel nuclear localization signal.^{240,241} IE1 dimerization is required for nuclear import. Once in the nucleus, IE1 interacts with the *hrs* of the virus DNA genome as suggested by co-localization of IE1 and DNA replication factors and the requirement of basic domain I for virus multiplication.^{228,238,306} As indicated by its requirement in plasmid replication assays and synthesis of virus DNA in infected cells (see later discussion), IE1 also contributes to viral DNA replication.^{253,271,273,307} However, the exact replicative functions of IE1 during infection are still unclear.

Baculoviruses encode additional transcription activators, including IE0, IE2, and PE38. Although these proteins are conserved among baculoviruses, the understanding of their roles during infection is limited. Derived by RNA splicing, IE0 is identical to IE1 except for an additional 54 residues, encoded by *exon 0*, at its N terminus. IE0 has redundant regulatory activities with IE1 and is dispensable for virus replication.^{52,178,206,255,275,300} IE2 is a 47-kDa leucine zipper, RING finger–containing transactivator.^{40,313,361} AcMNPV mutants containing loss-of-function *ie-2* alleles are viable, but exhibit delays in virus replication.²⁶² Upon overexpression in plasmid-transfected cells, *ie-2* causes cell-cycle arrest,²⁶³ but the significance of this activity is unknown. IE2 and the transregulator PE38 both localize to punctate nuclear

structures in transfected cells.¹⁸¹ PE38 is a promoter-specific transactivator with a leucine zipper and RING finger.^{180,203,252} AcMNPV *pe38*-deletion mutants exhibit reduced levels of DNA synthesis and BV production, but are viable.²¹⁷

LATE PHASE REPLICATION

The late phase of the baculovirus life cycle starts with viral DNA replication, which begins about 6 hours after AcMNPV infection. The synthesis of new genomic DNA and the expression of late structural genes are necessary for the production of BV, the infectious form generated during this period. Late gene expression is dependent on viral DNA replication. This dependence is illustrated by inhibiting viral DNA synthesis through use of a temperature-sensitive (*ts*) mutant in the essential helicase *p143* gene (see later discussion) that subsequently blocks late gene expression and eliminates BV production.¹⁰⁹ Likewise, RNA silencing (RNAi)–mediated ablation of viral DNA replication factors prevents AcMNPV DNA synthesis, blocks late viral transcription, and prohibits the characteristic shut-off of host protein synthesis (see later discussion).²⁸⁵ The molecular basis for the coupling of late gene expression to DNA replication is unknown, but is common among large DNA viruses.

At least six baculovirus genes, which include *p143*, *ie-1*, *lef-1*, *lef-2*, *lef-3*, and *dna pol*, are required for DNA replication (Table 73.2). These genes were originally identified using

TABLE 73.2 Baculovirus DNA Replication and Late Expression Factors

Virus gene	Essential ^a	DNA replication	Late expression	Function/homology	Virus mutants
<i>ie-1</i>	Yes	+	+	Transcription transactivator, DNA origin binding protein	<i>tsB821</i>
<i>ie-2</i>		+	+	Transcription transactivator, cell line–specific cell cycle regulator	
<i>p47</i>		–	+	Late RNA pol component	<i>ts317</i>
<i>p143</i>		+	+	Helicase, DNA binding, ATP binding motif	<i>ts8</i>
<i>dnapol</i>	Yes	+	+	DNA polymerase, 3'→5' exonuclease	
<i>pp31</i>		–	+	Virogenic stroma association	
<i>p35</i>	No	+	+	Apoptosis suppressor

^aGene is designated “essential” as determined by direct deletion or replacement within the AcMNPV genome.

transient DNA replication assays conducted in cultured cells with plasmids containing a viral *hr* enhancer/origin.^{169,205} Replication factors include a DNA binding helicase (p143), a putative primase (LEF-1), a primase-associated protein (LEF-2), a single-stranded DNA (ssDNA) binding protein (LEF-3), and a virus-encoded DNA polymerase. The essential function of these replication genes during infection has been confirmed through the analysis of conditionally lethal mutants and deletion mutants generated by using *Escherichia coli*–replicating bacmid technology (Table 73.2). Besides its transcriptional activities, IE1 promotes origin (*hr*)-specific plasmid DNA replication.^{169,205,271} A stretch of 23 residues at the IE1 N terminus is required for this activity.^{253,307} IE1's capacity to act as a DNA origin (*hr*)-binding protein and to stimulate homologous recombination suggests that it has a direct role in DNA replication,^{65,192,275} but its specific functions are still unclear. The *dna pol* gene³²⁰ is also essential for AcMNPV replication as demonstrated by the loss of virus viability upon its deletion.³²⁴ Other genes—including *ie-2*, *lef-7*, *pe38*, and *p35*—directly or indirectly stimulate replication in transient replication assays (reviewed in 204). Viral factors localize to centers of viral DNA replication within the virogenic stroma that forms within the nucleus (see later discussion).²³⁸ As these replication centers expand, host chromatin becomes marginalized to the inner edge of the nucleus; viral factors IE1, LEF-3, and helicase P143 in the presence of a viral *hr* element is sufficient for this marginalization.²²⁸

The precise mechanisms of baculovirus DNA replication are poorly understood. The *hr* repeats are likely origins of viral DNA replication,^{171,192,254,274} but this function has not been demonstrated formally. Non-*hr* sequences have also been implicated as genome replication origins.^{170,191,354} During infection, multiple unit-length genome fragments and concatamers of viral genomes have been detected.^{191,247} Although these potential replicative forms are consistent with a rolling-circle mechanism, no clear mechanism for DNA replication has emerged from various studies. Experimental evidence also suggests that recombination-dependent DNA replication contributes to the generation of baculovirus genomic DNA (reviewed by 277). For example, all baculoviruses encode an alkaline nuclease (*AN*) gene with sequence similarity to that of the phage lambda *red* exonuclease, which is involved in phage DNA recombination. Deletion of the alkaline nuclease gene *AN* from AcMNPV causes loss of virus viability even though viral DNA synthesis is normal.²³⁹ *AN* contributes to production of longer-than-genome length DNA fragments in infected cells, a property consistent with a role in recombination. The endonuclease and 5'→3' exonuclease activity of the alkaline nuclease may also participate in viral DNA maturation and packaging. Newly replicated, unit-length circles of DNA are packaged into individual nucleocapsids both within the virogenic stroma. Early in infection, one or more of the processes associated with viral DNA replication is sufficient to trigger DNA damage response and apoptosis.^{150,222,285} Baculovirus-encoded apoptotic suppressors (see later discussion) are necessary to block premature cell death caused by apoptosis and to allow completion of the virus's life cycle. Recent studies suggest that the host's DNA damage response is necessary for optimum viral DNA replication.^{150,222} For example, pharmacologic inhibition or RNAi-mediated ablation of the host kinases that signal the DNA damage response reduce AcMNPV DNA replication and severely restrict virus production. Thus,

baculoviruses likely modify specific aspects of the host's DNA damage response for their own benefit.²²²

Nineteen baculovirus genes are required for late gene expression (Table 73.2), as first determined for AcMNPV.^{197,205,271} These genes, designated late expression factors (*lefs*), were identified by their ability to support high-level expression of a reporter gene placed under control of a virus late promoter and *cis*-linked to an *hr* origin/enhancer element.²⁵² Due to the link between DNA replication and late gene expression, several genes required for late gene expression (*ie-1*, *p143*, *lef-1*, *lef-2*, *lef-3*, and *dnapol*) are essential DNA replication factors (Table 73.2). Because they are dispensable for late gene expression in certain cell lines, multiple *lefs* (*ie-2*, *lef-7*, and *hcf-1*) confer tissue or species specificity. In addition, a variety of viral genes contribute to host range, including helicase *p143* and host range factor-1 (*hrf-1*).^{48,64,164} Several *lefs* function directly or indirectly at the level of transcription or mRNA stabilization (Table 73.2). Of these genes, four (*p47*, *lef-4*, *lef-8*, and *lef-9*) encode components of the baculovirus RNA polymerase¹²³ that is specific for late and very late gene expression (see later discussion). The roles of transcription-specific *lefs* during infection have been characterized by using conditionally lethal mutations (Table 73.2).

The baculoviruses are unique among nuclear-replicating DNA viruses in that they switch to a novel RNA polymerase for late and very late transcription (reviewed by 251,277). The virus-encoded RNA polymerase retains specificity for late virus promoters *in vitro* and is distinguished from other host RNA polymerases by its resistance to α -amanitin and tagetitoxin, which are inhibitors of RNA pol II and III, respectively.^{100,107,152,357} The late RNA polymerase complex includes virus proteins p47, LEF-4, LEF-8, and LEF-9 as well as other proteins.^{16,123} The viral-encoded polymerase recognizes and initiates transcription within a nucleotide motif (A/G/T) TAAG that functions as the primary sequence element for late and very late promoter activity. All genes encoding proteins that are synthesized in abundance during the late phase (e.g., major capsid protein vp39, 6.9K basic core protein, gp64 EFP) possess this late TAAG motif. Fewer than 18 nucleotides surrounding this initiation site are sufficient to direct high-level late gene expression.²²⁴ Some late genes, including the *vp39* capsid gene, have multiple TAAG motifs, each of which serve as an independent RNA start site.³¹⁷ This redundancy boosts production of gene products needed in abundance for virion assembly. It is noteworthy that some early genes (*p35*, *gp64*, *pp31*, and *ie-1*) are also transcribed late in infection. Late transcription of these genes is often mediated by late TAAG motifs that overlap the early promoter elements.^{27,119,230,268}

VERY LATE PHASE REPLICATION

The final, very late stage of baculovirus infection is characterized by the hyperexpression of occlusion-specific genes and the production of mature OV from 18 through 76 hours after infection or until cell lysis (Figs. 73.3A and 73.5). The very late phase is marked by a dramatic increase in transcription of *polh*, which encodes the major matrix protein polyhedrin of OV. The very late hyperexpression of *polh* and its nonessential nature for BV production form the basis of the baculovirus expression vector system (see earlier discussion). Foreign genes are commonly placed under control of the *polh* promoter replacing the *polh* ORF to obtain high levels of expression very late in infection of cultured cells (recently reviewed by 159,260,321). The promoter

FIGURE 73.5. The very late occlusion stage of AcMNPV infection. Multiple OV particles (P) form on the inside edge of the hypertrophied nucleus near the inner nuclear membrane (NM). Dense fibrillar structures (FS) often form within the nucleus. The characteristic swelling of the nucleus forces the densely packed cytoplasm (C) to the cell's edge. (Electron micrograph courtesy of Dr. Peter Faulkner and Dr. Gregory Williams, Queens University.)

for the very late, hyperexpressed *p10* gene (see later discussion) has also been used.

The baculovirus-encoded RNA polymerase also mediates very late gene transcription. The promoters of the hypertranscribed genes (*polh* and *p10*) contain the late TAAG motif and are positively regulated by the 50 nucleotides constituting the noncoding leader of their gene (reviewed by 251,277). This region is responsible for the very late burst of transcriptional activity that distinguishes very late genes from late genes. These “burst” sequences may interact with activation factors responsible for the stimulation of transcription at this late time. Host and virus-specific factors likely participate in transcription of very late genes.^{251,277} Indeed, the baculovirus very late factor-1 (VLF-1) is a candidate for a positive activation.²¹² VLF-1 forms a complex with the burst sequences and stimulates very late transcription.^{221,360} Interestingly, VLF-1 is an essential protein (Table 73.2); in the absence of VLF-1, very late gene expression is compromised and viral DNA accumulation and packaging is reduced.³²³ Thus, VLF-1 may also contribute to viral DNA replication and nucleocapsid assembly.

p10 is the other very late, hyperexpressed gene of baculoviruses. It encodes a small 10-kDa coiled-coil domain protein that associates with expansive fibrillar structures (Fig. 73.5), which assemble in the nucleus and cytoplasm late in infection.²³² P10 is a nonessential protein that may disrupt the nuclear membrane or stabilize OV particles.^{329,349}

VIRUS ASSEMBLY, BUDDING, AND OCCLUSION

Nucleocapsids assemble during the late and very late phases of infection. New virus particles appear at the edge of the stromal matte located in the virogenic stroma (Fig. 73.1D), a poorly understood viral nucleoprotein structure centered within the nucleus. Consisting of DNA, RNA, and virus protein, the virogenic stroma is the likely site of viral DNA replication, conden-

sation, and encapsulation.^{90,362} As infection proceeds, the viral replication center (virogenic stroma) expands and host chromatin becomes marginalized to the nuclear periphery. This process involves the combined activities of the *ie-1*, *lef-3*, and *p143* genes and requires the presence of an *hr* element.²²⁸ Baculovirus phosphoprotein pp31 is a principal factor associated with the virogenic stroma; it binds DNA by a phosphorylation-dependent mechanism, but its exact function is unclear.^{36,118} pp31 appears to stimulate viral transcription rather than regulating viral DNA replication.³⁵⁹ Newly assembled nucleocapsids exit the nucleus by budding or transport through nuclear pores (Fig. 73.2) (reviewed in 277). Nuclear actin plays a critical role in the maturation of these nucleocapsids.^{47,108,237} The nuclear envelope is removed during transport to the plasma membrane. By interacting end-on with the plasma membrane, single nucleocapsids bud from the cell surface (Fig. 73.1C) and acquire the envelope fusion protein EFP GP64.²⁴⁵ The rate of BV release from AcMNPV-infected cells increases exponentially from 10 to 20 hours, then declines through 36 hours.¹⁹⁰

Late in infection, OV particles assemble and accumulate in the nucleus of infected cells (Figs. 73.3A and 73.5). For AcMNPV, OV production begins about 18 to 24 hours after infection and accelerates as production of BV declines. Not surprisingly, OV assembly involves multiple virus genes and events, including virus modification of nuclear membranes and vigorous import of polyhedrin into the nucleus (reviewed by 277). Nucleocapsids align along newly assembled membrane segments in the nucleus and subsequently acquire an envelope prior to encasement by polyhedrin (Fig. 73.1E). Studies of the generation of this nuclear membrane envelope and nuclear import of critical membrane proteins have revealed new facets to integral membrane protein trafficking.³³ OV formation is first observed on the inside edge of the nucleus (Fig. 73.5). Time-lapse video microscopy has suggested that the number of OV per cell is established early, and with time each particle increases in size.²¹⁰ Maturation of the OV includes deposition of the polyhedron envelope (calyx) over the particle's surface. Finally, OV are released upon disintegration of the nucleus and loss of plasma membrane integrity very late in infection.

Disease Progression in Insects

Horizontal transmission of baculoviruses is mediated by the OV, the form of the virus that is most stable and resistant to environmental degradation. Primary infection occurs in the midgut epithelium (Fig. 73.2) of the insect larva (reviewed in 29,277). Infection is initiated by larval ingestion of virus-contaminated food. Upon entry in the midgut lumen, the OV particles dissolve in response to the alkaline environment and release occlusion-derived virions (ODV). Passage of virus through the peritrophic membrane (Fig. 73.2) is facilitated by virus-encoded proteases (called enhancins), first discovered in the GV.¹⁹³ ODV subsequently bind to the brush border membrane of columnar epithelial cells and enter by direct fusion with the plasma membranes (Fig. 73.2). Infection proceeds by pathways comparable to that in cultured cells with the interesting exception that newly synthesized EFP GP64 is transported unidirectionally to the basal membrane side of the midgut cells (reviewed by 29,250). This targeting of GP64 allows nucleocapsid budding at the basal lamina and promotes rapid access of enveloped virus to the hemocoel and tracheal epithelium for systemic spread. Reduction of early GP64 synthesis selectively lowered the *per os* virulence of an AcMNPV mutant,³⁴³ suggesting an important role for this

directional transport. The production of OV in these midgut cells is rare for lepidopteran hosts. However, multiplication of certain baculoviruses, including mosquito NPVs, is restricted to the midgut. Thus, OV is produced there.²⁹

BV first generated in the midgut is next spread through infection of hemocytes (blood cells) and the epithelial cells that line the tracheal network.^{29,250} Interestingly, the lepidopteran baculoviruses encode *vfgf*, which bears sequence similarity to fibroblast growth factor. Recent studies with AcMNPV²¹⁴ suggest that *vfgf* activity in infected midgut cells activates extracellular metalloproteases that permeabilize the basal lamina, attracts susceptible tracheal cells, and allows BV to rapidly gain access to the trachea network and hemocoel. This secondary infection affects virtually all internal tissues of highly susceptible larva. Within several days, the larva is converted into a milky white liquid, consisting mostly of OV particles. This process, referred to as “melting” or “liquification,” is facilitated by a virus-encoded chitinase and a cathepsin, which cooperate to breakdown the larval cuticle (skin) that includes chitin.^{136,145} The activation and secretion of these enzymes is carefully regulated so as not to prematurely destroy infected cells or the larva before virus production is maximized.¹⁴⁵ A typical AcMNPV infection produces over 10⁸ OV particles, a yield that constitutes >10% of the dry weight of the insect. Upon rupture of the cuticular exoskeleton, OV are liberated into the environment. Liquification represents the successful conclusion to the baculovirus life cycle as the release of OV is required for virus spread through the host population. Nonetheless, there is limited evidence that baculoviruses establish persistent infections in some hosts.²⁷⁷

Baculovirus-Mediated Alterations of the Host

Besides causing mortality, baculoviruses can exert dramatic effects within their host. At the cellular level, infection induces major changes in the cytoskeleton and nucleus of infected cells (see later discussion). Transcription of most host genes is significantly reduced in AcMNPV-infected cells.^{243,281} Nonetheless, certain host proteins used by the virus are upregulated, including heat shock proteins, membrane trafficking proteins, and TATA-binding proteins.^{270,281} In general, host-protein synthesis declines rapidly after the onset of baculovirus DNA synthesis. When AcMNPV DNA replication is blocked, virus-mediated arrest of host-protein synthesis is prevented.²⁸⁵ Conversely, when AcMNPV late gene expression is selectively blocked, arrest of host-protein synthesis is unaffected. Because vDNA replication also triggers AcMNPV-induced apoptosis (see later discussion), the shutoff of host-protein synthesis and apoptosis may be caused by the same host-cell response to viral DNA synthesis. The biochemical mechanisms involved are not yet understood.

Remarkably, the baculoviruses also exert control of their hosts at the physiologic and behavioral level as a means to enhance virus production and dissemination (reviewed by 232,316). For example, baculovirus-infected larvae often display a classical behavior of wandering that involves climbing to the top of vegetation, where they succumb and liquefy while hanging from a leaf or branch. This strategy facilitates virus dispersal by wind and rain. A baculovirus-encoded protein tyrosine phosphatase gene (*ptp*) contributes to this virus-induced behavior.¹⁶⁶ Uninfected caterpillars in late stages of development also wander. Because this behavior is controlled by a cellular *ptp*, it is postulated that baculoviruses acquired a host ancestral *ptp* because of the conferred selective advantage for dissemination. In another striking example, baculoviruses block

development of their larval hosts by controlling the activity of ecdysone, the steroid hormone that triggers molting.²³³ The baculovirus *egt* gene encodes an ecdysteroid UDP-glucose/galactose transferase that is secreted from infected cells and transfers glucose or galactose to these ecdysteroids, thereby inhibiting uptake of the hormone by cells. Virus-encoded *egt* blocks larval molting (reviewed by 232,316), which is correlated with increased virus production; indeed, *egt* deletion mutants cause early mortality and yield less virus.²³⁴ The increased speed-of-kill of *egt* deletion mutants has already been adapted for the generation of engineered baculoviruses for improved insecticidal activity.¹⁵⁶ Interestingly, the inhibition of molting by baculovirus *egt* is also associated with enhanced wandering (climbing) of gypsy moth (*Lymantria dispar*) caterpillars upon infection with *Lymantria dispar* NPV.¹⁴⁷ The extent of this effect depends on virus dose and the developmental stage at the time of inoculation.

Baculovirus Manipulation of Apoptosis

The amazing replicative success of baculoviruses often depends on their capacity to suppress host-cell apoptosis, a dynamic suicide response that can function as an effective antiviral defense. As such, the baculoviruses have provided a wealth of information on the mechanisms by which viruses impede host apoptosis (also referred to as programmed cell death) to facilitate their multiplication (reviewed in 18,56,61). Moreover, these viruses have revealed highly conserved genes that regulate apoptosis in insects and mammals alike. Apoptosis is critical for many normal processes in animals, including development, differentiation, immune function, and elimination of damaged, oncogenic, or pathogen-infected cells. Thus, its misregulation is associated with many disease states (reviewed by references 101,332). By virtue of the discovery of multiple baculovirus genes that function as potent suppressors of apoptosis in phylogenetically diverse organisms, these viruses have provided valuable insight and important tools for studying the pathways by which apoptosis is either suppressed or amplified in human diseases and how apoptosis can be manipulated in treatment regimens.

Baculovirus mutants that lack suppressors of apoptosis trigger widespread, species-specific cell death.^{58,59,67,75,142,165,213} In some cases, apoptotic death approaches 95% of the infected cells within a 24-hour period, a response level that is unmatched by mammalian viruses. Baculovirus-induced apoptosis is characterized by premature cell death that includes activation of host pro-death components, fragmentation of host and viral DNA, and dismemberment of the cell into extracellular vesicles called apoptotic bodies (Fig. 73.3B). Accordingly, apoptosis severely limits production of virus. In the case of AcMNPV mutants deficient in apoptosis suppressors, virus yields are reduced as much as 10,000-fold in cultured cells.^{59,142} Moreover, the infectivity of these mutants in certain permissive insects (e.g., *Spodoptera frugiperda*) is 25- to 1,000-fold lower than that of wild-type virus.⁵⁹ This reduced infectivity is correlated with increased apoptosis in larvae and reduced virus spread.⁵⁵ Thus, apoptosis impedes baculovirus multiplication and can function as an effective antiviral defense in insects.

Cultured insect cells have proven invaluable in studies of baculovirus-induced apoptosis. In particular, lepidopteran *Spodoptera frugiperda* (SF21) cells and dipteran *Drosophila melanogaster* (DL-1 or S2) cells are now used as model systems for these studies and those of invertebrate apoptosis.^{43,58,59,149,187–189,210,227,285,286,290} Many of the cellular components comprising the apoptotic

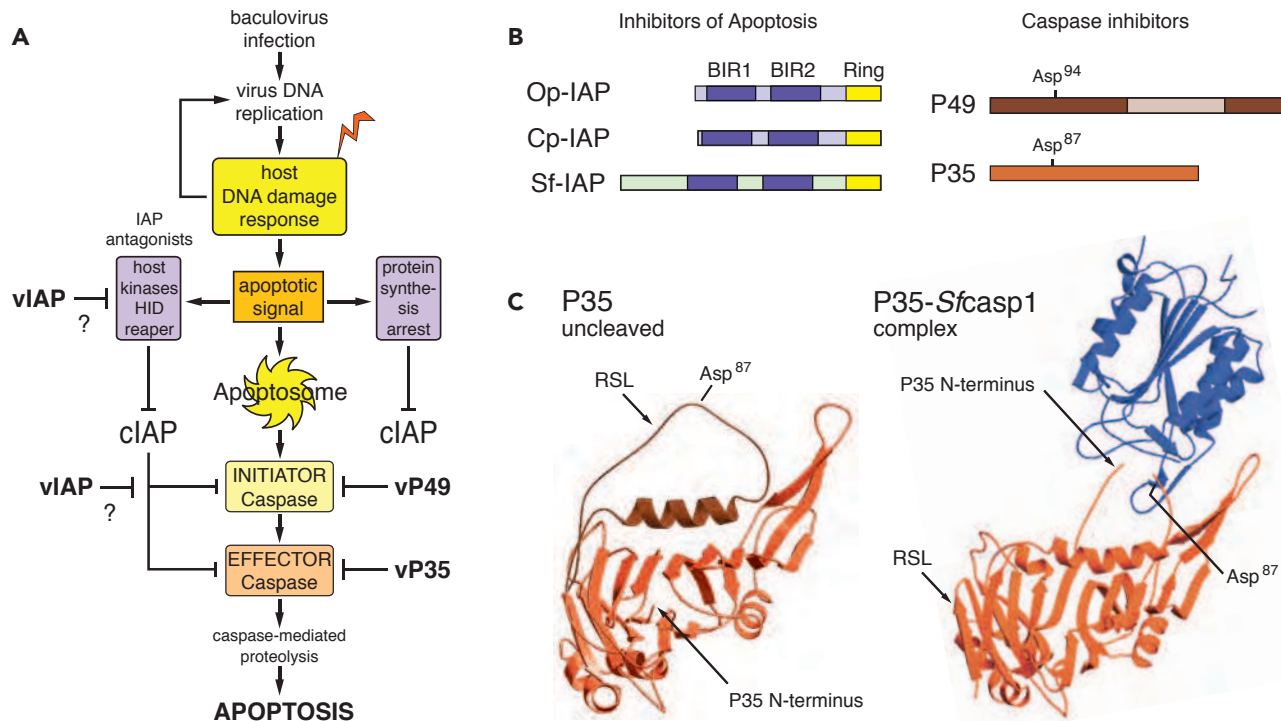

FIGURE 73.6. Baculoviruses and apoptosis. **A:** Model pathway for virus-induced apoptosis. AcMNPV triggers widespread apoptosis of model *Spodoptera frugiperda* (order Lepidoptera) cells due to events associated with viral DNA replication. Such replication triggers a DNA damage response, which produces an apoptotic signal that depletes host-cell IAP (cIAP). Loss of cIAP activates initiator and effector caspases, which if uninhibited cause proteolysis and apoptotic cell death. Virus-induced cIAP antagonists may be prodeath factors, like HID and reaper, activated host kinases, or the arrest of protein synthesis that accompanies baculovirus infection. Virus-encoded apoptotic suppressors produced early in infection prevent apoptosis. P35 inhibits active caspases, including *Sf*-caspase-1, whereas P49 inhibits an activated initiator caspase. Baculovirus-encoded IAPs block procaspase activation at an unknown (?) step upstream of P49. **B:** Baculovirus apoptotic regulators. The IAPs contain two BIR motifs and a C-terminal Ring finger motif. The viral IAPs, Op-IAP and Cp-IAP, closely resemble Sf-IAP, a cellular IAP from *S. frugiperda*. Caspase inhibitors P49 and P35 are 49% identical and contain aspartate residues (Asp⁹⁴ and Asp⁸⁷) required for caspase cleavage. P49 contains a 120-residue insertion (cross-hatched) unrelated to P35. **C:** Caspase inhibition by baculovirus P35. In uncleaved P35 (*left*), the prominent reactive site loop (RSL), with the Asp⁸⁷ caspase cleavage site at the apex, is solvent exposed while the N terminus is buried. During cleavage, P35 undergoes a dramatic conformation change (*right*) in which the RSL folds backward and the N-terminus is liberated so that it enters the active site of the targeted caspase, forming a stable, inhibited complex.

pathways of these cells have been identified (Fig. 73.6A). Moreover, these cells are sensitive to diverse apoptotic stimuli, including that caused by viruses, DNA-damaging agents, transcription and protein synthesis inhibitors, calcium ionophores, phosphatase inhibitors, and others. Nonetheless, baculovirus-permissive cell lines refractory to virus-induced apoptosis have been identified. For example, cultured *Trichoplusia ni* TN368 cells fail to undergo apoptosis upon infection with AcMNPV mutants that cause apoptosis of SF21 cells.^{59,142} The infectivity of these mutants in *T. ni* larvae is comparable to that of apoptosis-suppressing wild-type virus. The molecular basis of this interesting resistance to virus-induced apoptosis is unknown.

BACULOVIRUS-ENCODED APOPTOTIC SUPPRESSORS

To counteract the host suicide response and thus promote multiplication, baculoviruses have evolved novel apoptotic suppressors. These viral proteins regulate apoptosis at different steps in

the death pathway (Fig. 73.6A) and in a surprising diversity of organisms. Among different baculovirus species, two mechanistically distinct apoptotic suppressors have been identified: the caspase inhibitors (P35 and P49) and the inhibitor-of-apoptosis (IAP) proteins (Fig. 73.6B). The discovery of cellular IAPs with structural and biochemical properties comparable to those of viral IAPs suggests that baculoviruses originally acquired these apoptotic regulators from their insect hosts.^{43,151,289} It is likely that the same is true for the baculovirus-encoded caspase inhibitors, but no cellular homologs have yet been identified. The strong selective advantage conferred to baculoviruses by expression of an apoptotic suppressor, like P35,¹⁹⁴ is consistent with the acquisition and maintenance of such host genes. Interestingly, a single functional regulator per virus appears sufficient. For example, AcMNPV encodes one copy of the *p35* gene along with two nonfunctional *iap* genes.^{60,113} By contrast, OpMNPV encodes a single functional *iap* (Op-*iap3*), three nonfunctional *iaps*, and no *p35*.^{24,213}

Baculovirus P35 is a potent caspase inhibitor, often considered a universal suppressor of apoptosis due to its function in phylogenetically diverse organisms. First discovered in AcMNPV,⁵⁸ p35 prevents programmed cell death in plants, nematodes, flies, moths, and mammals (human cells included), among others, when expressed ectopically.^{18,56} Accounting for its widespread effectiveness, P35 (35 kDa) is a broad-specificity substrate-inhibitor of the effector caspases, which are the proteases that execute the cleavages, that dismember the apoptotic cell (reviewed by 39,101). P35 is cleaved by its target caspase at a requisite aspartate residue (Asp⁸⁷) and forms a stable, stoichiometric complex with it.^{17,37,364} The 2.2 Å crystal structure of P35 reveals that the Asp⁸⁷ cleavage site is located at the apex of a novel solvent-exposed reactive site loop (Fig. 73.6C), the orientation of which is critical to P35's anticaspase activity.^{86,366} Caspase-mediated cleavage induces a dramatic conformational change in the reactive site loop that stabilizes the covalent link between P35 and the caspase (Fig. 73.6C) in a novel mechanism for substrate-protease inhibition.^{69,358} Baculovirus P49 is a related substrate-inhibitor of the caspases. First identified in *Spodoptera littoralis* NPV,⁷⁴ P49 exhibits 49% amino acid identity with P35 (Fig. 73.6B) and likewise possesses a reactive site loop that is cleaved at a requisite aspartate residue (Asp⁹⁴) by the participating caspase. Interestingly, P49 targets apical initiator caspases in permissive insect cells. Thus, P49 inhibits the caspase(s) that proteolytically cleave and activate the effector caspases that are inhibited by P35.^{126,157,257,367} This target specificity is conferred in part by the cleavage site residues of P49.^{126,367} Thus, baculoviruses have evolved multiple caspase inhibitors with different specificities. A functional P35-like caspase inhibitor is also encoded by the insect entomopoxviruses.²¹⁵

The baculovirus IAPs were the first discovered members of the larger IAP family resident in diverse organisms and their viruses. The cellular IAPs are highly conserved regulators of cell fate that function during cell stress, immunity, tumorigenesis, and pathogen invasion (reviewed in 101,127,137,298,326). In insects, these short-lived (~30-minute half-life) cellular proteins regulate caspase activation and activity. The IAPs are defined by the presence of one or more essential baculovirus IAP repeat (BIR) domains (~80 residues), consisting of a conserved Zn²⁺-coordinating arrangement of Cys and His residues (CCHC). Many IAPs also possess a critical C-terminal RING domain, which functions as an E3-ubiquitin ligase.³²⁶ The antiapoptotic activity of some, but not all, IAPs is derived from the ability of the BIRs to bind directly to and neutralize initiator and effector caspases through ubiquitination by the RING. During apoptosis initiated by certain signals, the BIRs also interact with proapoptotic IAP binding motif (IBM) proteins, which bind to and dissociate the IAP-caspase complex to liberate active caspases and execute apoptosis.^{137,298,326}

Several insect virus families, including the baculoviruses, entomopoxviruses, iridoviruses, African swine fever virus, and the unclassified nudiviruses, encode functional and nonfunctional IAPs.^{18,56} Of these, the baculovirus IAPs are the best characterized. The viral IAPs share many structural and biochemical features with the cellular IAPs.^{43,151} However, despite these striking similarities and their potent antiapoptotic activity, the molecular mechanism by which baculovirus IAPs prevent apoptosis in insects is largely unknown. Current evidence suggests that viral IAPs use a mechanism that does not involve

direct inhibition of active caspases. The best-studied viral IAP is Op-IAP3 from *Orgyia pseudotsugata* NPV.^{18,24,56} This small, 268-residue IAP contains two BIRs and a C-terminal RING (Fig. 73.6B); each of these motifs is required for antiapoptotic activity.^{149,334,352} Upon its overexpression, Op-IAP3 blocks apoptosis triggered by various signals in cells from certain insects and mammals, suggesting that a broad and possibly conserved mechanism is involved.⁵⁶ In baculovirus-infected *Spodoptera* cells, Op-IAP3 functions upstream of baculovirus caspase inhibitors P49 and P35, thus likely inhibits initiator caspase activation.^{211,367} Op-IAP3 blocks the proteolytic activation of *Sf*-caspase-1 by an upstream initiator caspase.^{188,211,288} Nonetheless, in contrast to host insect IAPs, Op-IAP3 fails to bind and inhibit active caspases.³⁵³ The Op-IAP3 BIRs interact with *Drosophila* proapoptotic IBM proteins, including Reaper, Hid, and Grim.^{18,56,137,333,335} However, the relevance of these interactions is unknown since Op-IAP3 fails to block apoptosis in *Drosophila*.^{353,367} Interestingly, the Op-IAP3 BIRs mediate homo-oligomerization, which is also necessary for functionality of lepidopteran cellular IAP.^{43,149} Nonetheless, the target(s) and molecular mechanism by which the baculovirus IAPs function remains unresolved.

BACULOVIRUS-INDUCED SIGNALING OF APOPTOSIS

The signal for host-cell apoptosis originates early in the baculovirus life cycle. A critical link between virus DNA replication and the initiation of apoptosis has been established. Host caspase activation is one of the earliest events in the apoptotic cell. Caspase-mediated cleavage of viral caspase inhibitors P35 and P49 is first detected when viral DNA synthesis begins from 6 to 9 hours after infection with AcMNPV.^{17,367} Furthermore, P35 must be synthesized early in infection before viral DNA replication to effectively block virus-induced apoptosis.¹⁴³ Likewise, proteolytic activation of the proform of *Sf*-caspase-1, the principal executioner caspase in permissive *Spodoptera frugiperda* cells, coincides with the initiation of virus DNA replication.^{89,187,188,211,288} Thus, apoptotic signaling occurs before or during early viral DNA replication. Studies using viral DNA polymerase inhibitors and conditional AcMNPV mutants defective for viral DNA synthesis indicated that viral DNA replication or viral late gene expression was required to trigger apoptosis.^{60,187} Subsequent studies using RNA silencing for selective ablation of AcMNPV factors required either for viral DNA replication or for late gene expression demonstrated that viral DNA synthesis or events involving DNA replication, but not late gene expression, are required to trigger apoptosis.^{285,286} Thus, like vertebrate DNA viruses, baculovirus DNA replication events are sufficient to trigger the apoptotic response.

Recent studies have uncovered important facets by which baculovirus DNA replication triggers apoptosis. In invertebrates, the short-lived cellular IAPs are central regulators of apoptosis. In cell lines of dipteran and lepidopteran origin, a threshold level of IAP is necessary to block constitutive signaling towards apoptosis. Thus, when intracellular IAP drops below this level, caspases are activated and apoptosis ensues. Coincidental with the beginning of viral DNA synthesis, AcMNPV causes a dramatic loss of cellular IAP that forces caspase activation in lepidopteran and dipteran cell lines.³²⁵ This loss is independent of caspase activity and is conferred by residues within the N-terminal leader of the cellular IAP (e.g., SfIAP) and the ubiquitin ligase activity encoded by its C-terminal

RING domain.^{43,325} The AcMNPV *lef3* involved in viral DNA replication, but not those involved in late gene expression, are required for the virus-induced loss of cellular IAP. Thus, viral DNA replication likely triggers a host-cell response that depletes cellular IAP and executes apoptosis. The replication of vertebrate virus DNA can induce the host's DNA damage response, which triggers apoptosis (reviewed by 201,348). Thus, it is possible that baculovirus DNA replication is interpreted as DNA damage, which is a potent cause of apoptosis in insects as well. Indeed, AcMNPV DNA replication induces a DNA damage response in lepidopteran and dipteran cell lines.^{150,222} Additional study is required to determine the link between the DNA damage response and cellular IAP depletion in baculovirus-infected cells.

Host Transposons

The baculoviruses are one of the few families of animal viruses that accommodate the frequent and spontaneous insertion of host-derived transposable elements.⁹³ By virtue of their replication in the transposon-rich insect cell nucleus and the flexibility with respect to size of their DNA genome, baculoviruses are highly vulnerable to transposon insertion. This novel property has led to the identification of new families of transposons, which have been further developed as vectors for stable transformation of insects (see later discussion). Moreover, it is likely that baculovirus evolution has been significantly influenced by arthropod transposons, which represent potent insertional mutagens that generate genetic diversity and provide new genes to recipient viruses.^{130,277}

Baculovirus mutants with transposon insertions are often distinguished by altered plaque morphology, including the “few polyhedra” (FP) phenotype in which reduced nuclear accumulation of OV facilitates mutant identification by light microscopy. Several FP-causing lepidopteran transposons, including PiggyBac, IFP2.2, IFP1.6, TFP3, and Hitchhiker, have been identified by their insertion within or near the 25K protein gene (Ac61) of AcMNPV.^{13–15,42,91,92} Loss-of-function Ac61 mutants have reduced polyhedrin gene transcription and limited intranuclear envelopment of nucleocapsids that thereby lowers OV accumulation^{14,32,135}; the exact function of the highly conserved 25K protein is unknown. The most prevalent baculovirus-associated transposons possess terminal inverted repeats flanking a transposase gene with specificity for the sequence TTAA. For example, PiggyBac is a small (2.47-kb) autonomous transposon identified in the moth *T. ni*.⁹¹ It was the first nondrosophilid transposon used for stable germline transformation.¹²⁹ PiggyBac and other related transposons have now been used for gene transfer in Lepidoptera, Diptera, Coleoptera, and Hymenoptera, and most importantly in insect species (i.e., mosquitoes) of medical and agricultural significance for which P-element transformation has not been possible (reviewed by 130,231).

The retrotransposon TED (transposable element D) was also discovered as an insertion within AcMNPV.^{93,96,216,219} TED is a 7.5-kb, middle-repetitive retrotransposon that is actively transcribed within the AcMNPV-permissive host *T. ni*. Classified as an errantivirus (family *Metaviridae*), TED has a retrovirus-like organization with *gag*, *pol*, and *env* genes that are flanked by long terminal repeats. It is closely related to errantiviruses of other lepidopteran and dipteran (*Drosophila*) insects.^{96,216} Like a functional retrovirus, TED assembles virus-like gag-containing

particles, complete with protease and reverse transcriptase activities.^{128,195} The TED *env* gene also encodes a membrane-associated glycoprotein with properties expected of a retroviral envelope protein.²⁴⁸ Interestingly, the *env* gene of TED and other errantiviruses bear a striking similarity to the baculovirus Group II envelope fusion (F) proteins. Thus, it has been suggested that lepidopteran errantiviruses acquired their *env* gene from baculoviruses through an ancient integration/excision event.^{209,256} Not ruled out is the alternative possibility that baculoviruses have acquired *env* (F) genes through errantivirus insertion, as is the case for the AcMNPV insertion mutant-carrying TED.^{96,219} Nevertheless, the novel association between baculoviruses and active transposons has also led to speculation that virus-mediated shuttling of mobile genetic elements between insect species occurs in nature.^{93,277}

Polydnaviridae

Polydnavirus Structure and Classification

The polydnaviruses are large DNA viruses that are distinguished by their obligate and mutualistic association with their hosts, the endoparasitic wasps (Order Hymenoptera). The family *Polydnaviridae* derives its name from the taxonomically characteristic “polydisperse” DNAs that comprise the multisegmented genome of these novel viruses (reviewed by 20,185,302,344). Polydnavirus virions contain numerous double-stranded, supercoiled DNA molecules with sizes ranging from 2 to >30 kbp. The endoparasitic wasps that carry polydnaviruses transfer these virions to susceptible host caterpillars during oviposition (egg laying) in such a way that virus-encoded virulence genes compromise the caterpillar's immune response, facilitating development of the young wasp larva (see later discussion). Remarkably, virus multiplication and particle assembly occurs only in the wasp, not in the parasitized larva. Because virion DNA is generated from proviral DNA that is integrated within the host wasp genome, the polydnaviruses are transmitted vertically. The proviral DNA is also polydispersed within the wasp genome, where it is amplified and selected DNAs are packaged as circular segments within the virion.^{20,302} Recent sequence analyses of viral RNA transcripts expressed in ovaries (the site of virus replication) of polydnavirus-carrying endoparasitic wasps^{19,331} have revealed an unexpected relatedness between the polydnaviruses and the nudiviruses, which are large DNA viruses with an autonomous life cycle in insects (see later discussion). This possible relationship and the unique life cycle of the polydnaviruses have stimulated recent debate as to whether they fit the true definition of a virus.^{20,84,302}

The best-characterized polydnaviruses are from endoparasitic wasps. These predatory insects lay their eggs, accompanied by virus, in the body of a living insect larva, where the parasitic eggs hatch and the wasp's offspring develop. Polydnaviruses have been isolated from the *Ichneumonidae* and *Braconidae* families of wasps, and are correspondingly divided into two genera: ichtnoviruses and bracoviruses.^{20,185,302,345} The virus particles of these genera are morphologically distinct. The ichtnovirus virions are ellipsoid, with a uniform size of approximately 90 × 300 nm (Fig. 73.7); they resemble virions of the insect ascoviruses (see later discussion). The ichtnovirus nucleocapsid is enveloped by two unit membranes, one derived from the nucleus during virion morphogenesis and the other by budding from the plasma membrane of the host cell. In contrast, bracovirus virions consist of enveloped rod-shaped nucleocapsids with a uniform diameter (35–40 nm) and variable length (30–200 nm);

FIGURE 73.7. Morphologic features of polydnviruses. **A:** Schematic of an ichnovirus particle. An inner (IM) and outer (OM) membrane surrounds the nucleocapsid (NC). **B:** Electron micrograph of an ichnovirus. Inner and outer membranes envelope the lenticular nucleocapsids (NC) of uniform size. **C:** Electron micrograph of bracovirus in the calyx fluid (CF) of a female parasitoid wasp. A single membrane envelope (E) surrounds multiple nucleocapsids (NC) viewed end-on or laterally. An epithelial cell (EC) of the calyx is shown. (Micrographs courtesy of Dr. Donald B. Stoltz, Dalhousie University. Modified from Stoltz DB, Vinson SB. Viruses and parasitism in insects. *Adv Virus Res* 1979;24:125–171.)

they resemble the nucleocapsids of baculovirus and nudiviruses. Bracoviruses have a single membrane envelope, which is derived from the nucleus and surrounds one or more nucleocapsids (Fig. 73.7). Polydnvirus virions contain twenty or more different polypeptides associated with the nucleocapsid and the membrane envelope. These structural proteins are produced in the wasp through the expression of proviral DNA.^{20,185,302,345}

Polydnvirus Genome Organization

The polydnvirus genome is unique among animal viruses. It consists of an interrelated assortment of covalently closed, dsDNA circles that exist in multiple topologies that include superhelical and relaxed circular forms. The complete genomes of several bracoviruses and ichnoviruses have been sequenced to date. These and other studies have revealed that virion DNAs (designated by letters) are nonequimolar and polymorphic in length (reviewed by 185,302,345). For example, the 568-kbp genome of *Cotesia congregata* bracovirus (CcBV) consists of 30 dsDNAs ranging from 10 to >30 kbp.⁷⁷ Although each segment encodes at least one gene, a majority of the CcBV genome is comprised of non-coding DNA, in contrast to that of most autonomous DNA viruses. Not surprisingly, the aggregate size of polydnvirus genomes varies greatly and can be as large 600 kbp.³⁰² Many polydnvirus genes contain introns and thus resemble host genes. In the case of the ichnovirus prototype, *Campoletis sonorensis* polydnvirus (CsIV), the encapsidated 247-kbp genome is comprised of 24 nonredundant circular DNA segments.³⁴⁶ However, the CsIV genome also contains multiple redundant segments and a large number of repetitive elements. These higher-copy-number segments may provide increased expression of genes encoded therein. Each CsIV genome segment encodes at least one gene, but also contains portions that are homologous to other segments. Several of the ichnovirus segments are likely derived by recombination from larger segments and are thus described as

“nested” segments.^{185,302,345} This phenomenon also increases the copy number of certain virulence genes.

Until recently, the origin of the polydnviruses has remained an enigma. Nucleotide sequence analyses indicated that encapsidated DNA genomes of the bracoviruses and the ichnoviruses lack many genes that are characteristic of known virus families, including those genes involved in DNA replication.^{20,302} Instead, the virion-packaged DNAs encode several novel gene families that contribute to the pathology and immunomodulation by these viruses in the parasitized host (see later discussion). Thus, in the absence of any virus multiplication outside the wasp itself (i.e., in the parasitized larva), replicative genes appear dispensable. The recent surprise concerning the origin of polydnviruses, specifically the bracoviruses, is the finding that provirus genes expressed in the wasp ovaries include a set of 22 genes that are most closely related to those encoded by the autonomous nudiviruses that also infect lepidopteran caterpillars.¹⁹ Of these bracovirus genes, 14 individual genes exhibit sequence similarity to those baculovirus genes that contribute to virus late gene transcription, viral DNA packaging, particle assembly, and membrane envelopment of virions. However, there is no evidence for expression of those genes known to contribute to baculovirus DNA replication, such as the *lef* encoding DNA helicase, DNA polymerase, or DNA binding proteins. These findings and others support the notion that the polydnviruses evolved from an ancestral nudivirus that had established a persistent infection in the braconid wasps.^{20,302} In contrast, similar sequence analyses of nonencapsidated ichnovirus structural genes that are expressed in ovaries of ichneumonid wasps³³¹ failed to identify any relationships with nudivirus genes. Thus, the ichnoviruses may have evolved from a yet-to-be-identified ancestral virus unrelated to the bracoviruses.

Proviral DNA of the polydnviruses is present as integrated segments that are clustered at different loci of the wasp

genome; thus, the provirus is inherited in a Mendelian fashion. The mechanisms by which the polydnavirus genome is amplified, excised, and packaged into virus particles are poorly understood.^{185,302,345} Evidence exists that proviral DNA segments within the wasp genome are amplified before excision and encapsulation. Where the relationship between virion and proviral DNA is known, the largest or “master” DNA segments within the wasp genome are flanked by direct repeats. For example, the 16-kbp integrated W segment of CsIV is flanked by 1.2-kb repeats.^{66,185} Within the W segment, additional 350-bp repeats generate nested segments R and M, apparently by homologous recombination during amplification in the female wasp. In the wasp genome, CsIV segment B is flanked by 59-bp direct repeats that are removed during excision and circularization.⁸⁸ This finding and others are consistent with a mechanism in which CsIV proviral segments are excised from the wasp genome, possibly by recombination, prior to amplification.¹¹⁴ The presence of chromosomal sites lacking proviral

DNA in tissues that accommodate viral replication is consistent with this later mechanism.¹¹⁴

Polydnavirus Functions in the Wasp's Life Cycle

Polydnaviruses play a critical role in the life cycle of endoparasitic wasps. Moreover, these integrated viruses depend on the wasp for their survival. Thus, the mutualistic interaction between virus and wasp is a central determinant of the genetic composition and multiplication strategy of these novel viruses. Polydnaviruses multiply in the oviducts of female wasps as a normal step in the development of the reproductive tract (Fig. 73.8). Virus multiplication is under hormonal control and initiates during development of the wasp as a pupa.^{185,302,345} Virus DNA production, encapsidation, and virion assembly occurs primarily in the nuclei of epithelial calyx cells of the wasp's oviducts (Fig. 73.8). In mature females, the virions are released from the calyx cells into the oviduct lumen, either by budding (ichnoviruses) or by cell lysis (bracoviruses). Polydnavirus particles accumulate to high

FIGURE 73.8. Polydnavirus transmission.

Polydnavirus particles form in the epithelial cells of adult female ovaries and are released into the calyx fluid (*top inset*) where they accumulate to high densities. In the first step of parasitization (*top*), the wasp egg is injected along with virus and venom into a lepidopteran larva during oviposition. During endoparasitic development (*bottom*), polydnavirus-encoded gene products suppress the larval immune response allowing the wasp egg to develop. After parasitization, the wasp larva spins a cocoon, pupates, and emerges as an adult to repeat the process. (Courtesy of Dr. Bruce A. Webb, University of Kentucky; modified with permission.)

density in the calyx fluid (Fig. 73.7C) and are deposited along with the egg and other wasp secretions in the target larva during oviposition. Virus gene expression in the wasp differs from that in parasitized caterpillar hosts.^{28,185,302,314} Despite the presence of high concentrations of virions, polydnviruses cause no obvious pathology in provirus-carrying wasps. The predominant form of viral DNA in males is the integrated provirus.

Polydnvirus Modulation of Larval Responses During Parasitization

Upon oviposition, the female wasp delivers her egg accompanied by virus to the recipient caterpillar (Fig. 73.8). The caterpillar normally mounts an immune response that encapsulates and destroys the intruding egg in a process mediated in part by hemocytes of the larva's circulatory system. However, in the case of polydnvirus-carrying ichneumonid and braconid wasps, the virus suppresses encapsulation and other aspects of the larva's immune response, which allows proper development of the wasp's offspring. In experiments in which the egg is artificially injected into the larva in the absence of virus, the egg is destroyed, demonstrating a definitive role for virus-mediated abrogation of the larva's immune response.⁷⁶ Thus, the relationship between polydnvirus and wasp is mutualistic: the wasp egg requires the virus for protection from the immune response of the recipient larva and the virus requires survival and proper development of the wasp for its own perpetuation.

The most obvious physiologic effect of the polydnviruses is in the parasitized insect host, in which larval immunity and development are altered.^{185,302} Neither virus replication nor virus assembly occurs in parasitized larva. However, virion DNA is long lived and viral RNA transcription occurs throughout parasitization, principally in larval hemocytes and fatbody (the equivalent of the vertebrate liver). In caterpillars, the primary immune response to parasitization is encapsulation of the wasp egg and includes direct attachment of larval hemocytes in layers. Polydnviruses suppress encapsulation by altering the physiology of the capsule-forming hemocytes (granulocytes and plasmatocytes).^{302,345} Some polydnvirus gene products are secreted and may affect surrounding hemocytes and tissues. In the case of *Microplitis demolitor* bracovirus (MdBV), virus-induced apoptosis kills a subclass of hemocytes that mediate the encapsulation response.³⁰³ Nonetheless, some hemocytes survive to express polydnvirus genes that alter their function.

Polydnviruses carry the genes for suppression of the caterpillar's immune response.^{185,302,345} Multiple gene families contribute to immunomodulation. This repetition and variation of related pathogenicity genes may enhance expression levels or facilitate tissue targeting during parasitization.²⁸ One such gene family expressed during parasitization includes the viral ankyrin (*vankyrin*) genes, which encode factors with ankyrin repeat domains belonging to the I κ B family of proteins.^{184,318} Two *vankyrin* genes of MdBV exhibit normal I κ B activity by inhibiting NF- κ B responsive genes when exogenously expressed in *Drosophila* cells.³¹⁸ Suggestive of their importance in immunomodulation, *vankyrin* genes are encoded by both the ichnoviruses and the bracoviruses. NF- κ B is an important regulator of insect genes encoding antimicrobial peptides and factors involved in cellular immunity (reviewed by 61,302). Thus, the I κ B-like activity of the *vankyrins* could disrupt NF- κ B activation of these immune response genes in the parasitized larva. Polydnviruses also carry a family of genes (*ptp*) that encode tyrosine

phosphatase-like proteins (PTPs). Cellular PTPs regulate receptor-mediated signal transduction pathways, suggesting that the virus-encoded PTPs function similarly to downregulate the immune response. Two bracovirus *ptps* are involved in suppression of encapsulation and phagocytosis.^{266,304} Polydnviruses pathogenesis genes can also have either proapoptotic or antiapoptotic effects on lepidopteran cells,^{79,304} suggesting that virus-mediated control of apoptosis contributes to immunosuppression. Other polydnvirus-encoded immunomodulator genes, including those predicted to encode epidermal growth factor-related proteins, cysteine-rich motif proteins, vinnexin, and *rep* proteins, have been identified.^{77,185,302,345}

Ascoviridae

Classification and Structure of Ascoviruses

Ascoviridae is a family of large DNA viruses that primarily infect insects of the order Lepidoptera (moths and butterflies) and cause a slow, fatal disease.⁸³ The name ascovirus is derived from the Greek word *askós* (sac), which describes the large membrane-bound vesicles that are associated with virus development. The formation of these virion-containing vesicles represents the family's distinguishing feature⁸¹ and is critical to the virus's dissemination strategy that involves endoparasitic wasps (see later discussion). The ascoviruses are one of the newest DNA virus families to be discovered, with only five different species identified to date. Depending on the species, ascovirus particles are reniform (kidney-like) or bacilliform in shape (Fig. 73.9A). The virions (~400 × 130 nm) have an electron-dense core surrounded by two unit membrane envelopes (Fig. 73.9B). At least 21 different proteins, ranging in size from 9 to 120 kDa, are present in virions of the prototype ascovirus, *Spodoptera frugiperda* ascovirus 1a (SfAV).³⁰⁸ The ascovirus genome is a double-stranded circle of DNA ranging in size from ~116 to 186 kbp, depending on the species (reviewed in 83). Nucleotide sequences indicate that the ascovirus family is unique but exhibits some relatedness to the invertebrate iridoviruses.²²

Stages of Ascovirus Replication

The first visible sign of ascovirus infection is hypertrophy of the cell and its nucleus; the infected cell's diameter can increase up to 10-fold.⁸² The nucleus subsequently fragments and the infected cell is divided into 20 to 30 membrane-bound vesicles containing assembling virions (Fig. 73.9C). This process involves extensive invagination of the plasma membrane and mimics that which occurs during apoptosis. Once virus-containing vesicles dissociate from the infected cell, they are released into the larva's hemolymph. The larva's basement membranes are then disrupted and the hemocoel fills with ~10⁸ vesicles per ml, which gives the hemolymph a distinguishing milky white color.⁸¹ These vesicles with their associated virus are subsequently picked up during the egg-laying process by the ovipositor of an endoparasitic female wasp.

Interestingly, a host-like effector caspase encoded by the ascovirus SfAV likely contributes to this unusual vesicle formation during infection.²¹ Thus, the ascoviruses may have exploited host-cell apoptosis as a means to expedite virus transmission by endoparasitic wasps (see later discussion). *Heliothis virescens* ascovirus (HvAV) also encodes a caspase, but multiplication in cell lines fails to induce comparable vesicle formation.³ Thus, the role of ascovirus caspases or that of the host's caspases during larval infection remains to be clarified. The

The electron micrograph shows that the surface of the kidney-shaped particle has a reticular texture. **B:** Cross-section of two *Scotogramma* ascovirus virions. A multi-layered membrane surrounds the nucleocapsid. **C:** Intracellular vesicles formed during ascovirus infection. Dark-staining bodies are membrane-bound vesicles (VM) that contain *Autographa precationis* ascovirus particles (white arrowheads). The VM are bordered by a basement membrane. (**A** courtesy of Dr. Brian A. Federici, University of California–Riverside, and Dr. J. J. Hamm, USDA–ARS, Tifton, GA; **B** modified from Federici BA. A new type of insect pathogen in larvae of the Clover cutworm *Scotogramma trifolii*. *J Invertebr Pathol* 1982;40:41–54; and **C** modified from Federici BA, Hamm JJ, Styer EL. Ascoviridae. In: Adams JR, Bonami JR, eds. *Atlas of Invertebrate Viruses*. Boca Raton, FL: CRC Press 1991:339–349.)

ascoviruses encode several lipid metabolism enzymes, which may also contribute to vesicle production.⁸³

To date, ascovirus replication mechanisms are poorly understood. Multiplication in lepidopteran cell cultures has revealed possible roles for viral and cellular microRNAs in regulation of HvAV (reviewed by 5). Interestingly, HvAV and other ascoviruses encode an RNase III gene, which exhibits nuclease activity for dsRNA and appears to be essential for virus multiplication.¹⁵⁴ Encoded by few other viruses, RNase III proteins play an important role in RNA silencing.

Ascovirus Transmission, Disease, and Host Range

In nature, the principal transmission route of ascoviruses involves endoparasitic wasps, which carry virus-containing vesicles on their ovipositor as a result of egg laying. In the laboratory, ascovirus inoculation is accomplished by pricking the host larva with a needle bearing virus-containing vesicles.⁸³ A dose of 10 larva-derived vesicles is sufficient for 90% infection. The viruses cause a slow, chronic infection in larvae or pupae. The disease causes reduced feeding, developmental arrest, and death within 2 to 6 weeks. There is little obvious pathology during the early stages of infection. Some larvae exhibit the characteristic milky discoloration. The host range of ascoviruses may include only a few closely related insect species, mostly of the order Lepidoptera (reviewed in 83). However, the lack of obvious pathology early in infection may mean that the host range is broader than that suggested by entomologic surveys. Of the ascoviruses studied to date, *Diadromus pulchellus* ascovirus (DpAV) multiplies both in its lepidopteran hosts and at low levels in the reproductive tract of the ichneumonid wasp *D. pulchellus*. A mutualistic relationship between

DpAV, the most divergent of the ascoviruses, and its wasp vector is suspected.^{23,83}

Nudiviruses

Classification, Structure, and Genomics of the Nudiviruses

Historically, the nudiviruses were thought to be nonoccluded baculoviruses because of their common characteristics, including rod-shaped nucleocapsids, a circular, dsDNA genome, and nuclear replication.³⁸ However, nucleotide sequence analyses indicated that the nudiviruses are only distantly related to the baculoviruses (reviewed by 342). Thus, a new genus *Nudivirus* has been proposed to accommodate these novel insect pathogens. Of the five species characterized to date, these viruses have been isolated from most of the major insect orders, suggesting an ancient co-evolution of the nudiviruses and their insect hosts.

Varying in size from 97 to 230 kbp, the nudivirus DNA genome is packaged into a nucleocapsid that is surrounded by a membrane envelope acquired within the nucleus and one obtained upon budding from the plasma membrane. As determined from the four nudiviruses sequenced to date, a core of 33 genes is conserved. Of these genes, 20 exhibit sequence similarity with baculovirus genes that are involved in transcription, DNA replication, and nucleocapsid composition or assembly.³⁴² Nudivirus replication mechanisms are poorly understood, thus the functions of these similar genes are unknown. Although existing as nonoccluded viruses, certain nudiviruses also possess a gene related to polyhedrin or granulin used by baculoviruses for occlusion. It is interesting to speculate that this occlusion-like gene is the remnant of a common ancestor of the nudiviruses and baculoviruses.

Nudivirus Latency and Transmission

Originally isolated from a *Heliothis zea* (corn earworm) cell line, HzV-1 is one of the best-characterized nudiviruses. Its genome is a large (~228 kbp) circle of dsDNA⁵⁰ that has limited sequence similarity to certain baculovirus genes, confirming its very distant relationship to *Baculoviridae*. A hallmark of HzV-1 is its capacity to establish persistent or latent infections.³⁸ HzV-1 persistence involves stable integration of the genomic DNA and low-level, spontaneous replication of virus that can cause lytic infection of naive cells.²⁰² The establishment of viral persistence or latency is associated with the presence of a single 2.9-kb HzV-1 RNA transcript, designated the persistency-associated transcript (PAT1).⁴⁶ PAT1 is a noncoding RNA that is the only HzV-1 RNA detected during latency. Recent evidence suggests that PAT1 suppresses the HzV-1 *hhi-1* gene by a mechanism that involves the generation of microRNAs that target and destabilize *hhi-1* RNA transcripts.³⁵⁶ Transcription of HzV-1 *hhi-1* gene occurs early in infection and mediates reactivation from latency, thereby contributing to a productive infection.³⁵⁵ Consequently, HzV-1 may use microRNAs derived from its single latency transcript in an RNA interference mechanism that is required for establishment of latency.³⁵⁶ Thus, HzV-1 will serve as a useful model for mechanistic studies of insect virus latency.

Oryctes virus is another notable nudivirus. Distinguished by its unique tail-like structure protruding from one end, this 128-kb DNA virus shares many genes with other nudiviruses and certain replication, transcription, and nucleocapsid genes with the

baculoviruses.³⁴¹ Oryctes virus causes fatal infections of the rhinoceros beetle *Oryctes rhinoceros*, which is a serious pest species of palm trees in Southeast Asia and the Pacific region.¹⁵⁸ Consequently, this virus is a very effective biologic control agent used in coconut and palm oil plantations of the area. Virus is transmitted by contaminated food sources or mating. Typical of most nudiviruses, little is known about its replication mechanisms.

Nodaviridae

Classification and Host Range of Nodaviruses

Members of the family *Nodaviridae* are small RNA viruses with a single-stranded, positive-sense genome consisting of two RNAs. The bipartite genome is packaged within a single, non-enveloped virion (~30 nm dia) with T = 3 icosahedral symmetry (reviewed in 10,12,327). The genome organization and replication strategy of the nodaviruses is among the simplest of known viruses (Fig. 73.10). As such, the nodaviruses are powerful models for exploring strategies of virus replication, virion assembly, host interactions, and RNA silencing.

The nodaviruses are divided into two genera, the alphaviruses and betanodaviruses, which infect insects and fish, respectively. The family name originated from Nodamura virus, which was first discovered in mosquitoes near the Japanese village of Nodamura.²⁸² The best-studied insect nodaviruses include flock house virus (FHV), black beetle virus (BBV), Nodamura virus (NoV), and Wuhan nodavirus (WhNV). These viruses were isolated from the grass grub *Costelytra zealandica* (Coleoptera) in New Zealand; the scarab beetle *Heteronychia arator*

Nodavirus genome organization

FIGURE 73.10. Nodavirus genome organization and assembly. Positive-sense genomic RNAs 1 and 2 encode the replicase (protein A) and capsid precursor protein (protein α), respectively. RNA 1 also generates subgenomic RNA 3, which encodes protein B2, a suppressor of host-cell RNA silencing. Assembled from capsid precursor α , provirions undergo a maturation cleavage producing capsid proteins β and γ . Infectious virions contain an equimolar ratio of genomic RNA 1 and 2.

(Coleoptera), also in New Zealand; the mosquito *Culex tritaeniorhynchus* (Diptera) in Japan; and the small cabbage white butterfly *Pieris rapae* (Lepidoptera) in China, respectively.³²⁷ Most members of the alphanodavirus genus were isolated from insects of Australasia. Other alphanodaviruses include Pariacoto virus (PaV), New Zealand Virus, Boolarra virus, and Manawatu virus. NoV is the only nodavirus with the capacity to multiply in vertebrates.¹⁰ Nonetheless, upon transfection of their genomic RNA, many nodaviruses can replicate in cells from highly diverse organisms, including mammals, nematodes, plants, and the yeast *Saccharomyces cerevisiae*.^{7,207,261,287}

Nodavirus Virion Structure

The nodaviruses have provided enormous insight into icosahedral virus assembly and maturation. The structures of BBV, FHV, NoV, and PaV have been determined at atomic resolution (see images at <http://virology.wisc.edu/virusworld/> or <http://viprdb.scripps.edu/>),^{12,87,148,309,365} Each virion contains 180 copies of the same capsid protein (Fig. 73.10A). Sixty triangular units, consisting of three similarly folded capsid proteins, form an icosahedral lattice with $T = 3$ symmetry.^{160,283} Three capsid proteins form a prominent peak at the quasi-threefold axis. At the twofold axes, conserved C-terminal residues of the capsid protein make contact with duplexed genomic RNA that is highly ordered and stabilize the capsid protein interface.⁸⁷ The crystal and cryomicroscopy structures of nodaviruses, including that of PaV and FHV, reveal a dodecahedral cage of ordered dsRNA (Fig. 73.11B) that constitutes 35% (1,500 nucleotides) of the ssRNA genome.^{309,319} The RNAs interact extensively with the basic N-terminal region of the capsid protein as well. However, the ordered RNA structure does not require a specific nucleotide sequence to form. Interestingly, C-terminal residues of the capsid protein are required for RNA encapsulation.³²⁷ At the fivefold axis, the capsid proteins form a pentameric helical bundle that has been proposed to participate in release of the genomic RNA upon virus penetration into the host cell's cytosol.⁵¹

The nodavirus provirion is assembled from 180 copies of the ~43-kDa capsid precursor α . During virion maturation (Fig. 73.10), α is cleaved very near its C terminus to generate capsid proteins β and γ .^{99,105} For FHV, this autocatalytic post-assembly cleavage occurs between residues Asn³⁶³ and Ala³⁶⁴, which are located on the inside surface of the virion. This cleavage event is required for infectivity and virion stability.^{105,284} Either this maturation cleavage or the liberated γ peptide may also contribute to virus uncoating and release of the genomic RNAs into the cytosol (see later discussion).

Nodavirus Genome Organization

The nodavirus genome consists of two single-stranded, messenger-active RNAs, designated RNA 1 and 2, that are 7-methyl GpppN capped, but not polyadenylated (Fig. 73.10). The 3' ends of both RNAs have an unknown structure or unidentified factor attached. RNA 1 (~3.1 kb) encodes the functions required for RNA transcription and replication, whereas RNA 2 (~1.4 kb) encodes the coat protein. Both RNAs are required for infectivity and are packaged within the same virion.³²⁷ Functions of the genomic RNAs were determined by using heterologous expression systems, which include baculovirus vectors, vaccinia virus vectors, transformed yeast, and transfected *Drosophila* cells. RNA 1 carries all the information necessary for autonomous replication.¹⁰⁴ It encodes at least two polypeptides:

proteins A and B2 (Fig. 73.10). Protein A (~112 kDa) is an RNA-dependent RNA polymerase (RdRp) that is required for virus RNA replication.^{9,104} Encoded by the 3' end of RNA 1, protein B2 (~12 kDa) is translated from subgenomic RNA 3 (Fig. 73.10), which is abundant in infected cells, but not packaged into virions.^{97,116} Protein B2 is a suppressor of host-mediated RNA silencing (see later discussion). Nodavirus genomic RNA 2 encodes the capsid precursor protein α (Fig. 73.10). Thus, the functions necessary for genome replication (RNA 1) and virus transmission (RNA 2) are segregated onto different genetic elements.

Stages of Nodavirus Replication

FHV, the best-studied nodavirus, and its close relative BBV multiply prolifically in *Drosophila melanogaster* cell lines,³²⁷ providing a highly tractable system in which to dissect virus replication. It is likely that FHV enters the host cell by receptor-mediated endocytosis. However, the *Drosophila* receptor remains to be identified. The acidity of the endosome triggers an irreversible exposure or release of the capsid γ peptides, which disrupts the endosomal membrane and facilitates release of the genomic RNAs into the cytoplasm.³³⁶ Required for membrane penetration, the lipophilic γ peptide is generated by autoproteolytic cleavage of capsid protein precursor α within the assembled virion.^{11,236} Subsequent viral multiplicative events occur in the cytoplasm. Uncoated genomic RNA 1 is translated to produce the protein A-containing RdRp. Newly synthesized viral RNAs are detected within 2 hours after inoculation and continue to accumulate through 20 hours. By then viral RNA represents up to 50% of the total cellular RNA, an astounding level considering that it is comparable to that of ribosomal RNAs.^{98,99,105} Protein A-mediated viral RNA replication occurs on the outer mitochondrial membranes. In particular, replication occurs within newly formed 50-nm diameter membrane-bound spherical structures (spherules) that are comparable to those formed during replication of other positive-strand RNA viruses.²¹⁸ Protein A and replicating FHV RNA are required for spherule formation; proteins B2 and capsid proteins are dispensable.¹⁷³ It is estimated that within each spherule there are three RNA replication intermediates and an average of 100 membrane-associated protein A molecules, which self-interact.¹⁷² A single neck-like portal, which is large enough to accommodate messenger-active RNAs, connects these virus-induced spherules to the outside cytoplasm. Mitochondrial phospholipids and cellular chaperones are critical for FHV RNA replication in transfected yeast cultures, thus are also likely important for virus multiplication.^{299,347}

During infection, nodavirus RNA synthesis is temporally regulated. Late in infection, the replication of genomic RNA 1 and 2 is coupled, which ensures production of an equal molar ratio of both RNAs required for virion packaging. However, early in infection, subgenomic RNA3, which produces B2 to suppress the host RNAi response, transactivates RNA2 replication.⁸ As the level of RNA2 increases, it represses RNA3 production¹⁰⁴ through a feedback inhibitory mechanism.³²⁷ Not surprisingly, nodaviruses generate their plus-stranded genomic RNAs through (–) RNA intermediates. *Cis*-acting sequences required for plus- and minus-strand RNA transcription and RNA 3 suppression have been identified.¹⁰ The FHV RNA 1 nucleotides that direct synthesis of this self-replicating RNA and its recruitment to the mitochondrial membranes have also been defined.³²²

FIGURE 73.11. Comparison of nodavirus and tetravirus structures. **A, top:** Image reconstructions of a T = 3 nodavirus (flock house virus) and a T = 4 tetravirus (*Nudaurelia capensis* ω virus). The average particle diameter for the nodaviruses and tetraviruses is 320Å and 415Å, respectively. **A, bottom:** Subunit arrangement of the nodavirus (T = 3) and the tetravirus (T = 4) virions. Each subunit is indicated by a trapezoid. Nodaviruses contain 60 subunits of three similarly folded capsid proteins (A, B, and C) that form a prominent peak at the quasi-threefold axis (*top image*). Tetraviruses contain 240 capsid protein subunits (A, B, C, and D), in which 12 subunits comprise each triangular face of the virion. (See images at <http://virology.wisc.edu/virusworld/> or <http://viperd.b.scripps.edu/>.) **B:** Arrangement of genomic RNAs within the virion of the nodavirus *Pariacota* virus. The symmetrically arranged shell of helical RNA (*lighter*) contacts capsid proteins on the inside surface of the virion (*darker*). (Adapted with permission from Dr. John E. Johnson, Scripps Research Institute, La Jolla, CA. Images of *Pariacota* virus courtesy of Jean-Yves Sgro, Institute for Molecular Virology, University of Wisconsin–Madison.)

Translation of nodavirus RNA 2 yields abundant levels of the capsid precursor α , which is cleaved during capsid assembly (Fig. 73.10). Despite equal intracellular levels of RNA 1 and 2, synthesis of capsid protein α predominates late in infection as a direct result of the ability of RNA 2 to outcompete RNA 1 for rate-limiting translation factors.⁹⁸ As capsid precursor α accumulates, an equimolar ratio of RNA 1 and 2 are packaged within the nodavirus provirion; the mechanism ensuring this

stoichiometry is unknown.¹⁸³ Before cell lysis, extraordinary yields of assembled particles (2 mg per 10^8 cells) accumulate in the cytosol of the infected cell and extensive crystalline arrays in the cytoplasm are often observed. Owing to the segmented genome, reassortment of genomic RNAs has been detected upon mixed infections of cultured cells. Moreover, nodaviruses can generate defective interfering particles and can establish persistent infections in cell cultures.^{162,327}

Permissive *Drosophila* cells respond to nodavirus FHV infection by undergoing caspase-dependent apoptosis.²⁹⁰ Both alphaviruses and betanodaviruses have the capacity to trigger apoptosis during multiplication.^{125,290} FHV-mediated depletion of the endogenous inhibitor-of-apoptosis DIAP1 triggers apoptosis in *Drosophila*, as it does during baculovirus-induced apoptosis in these cells.^{290,325} Because host caspases are not required for nodavirus assembly or maturation, the process of apoptosis and the resulting membrane-protected vesicles may facilitate virus release and subsequent dissemination to tissues within the host insect.

Nodavirus Suppression of Host RNA Silencing

Nodaviruses have also provided important understanding of the molecular mechanisms by which RNA viruses trigger the antiviral RNA silencing response in host cells and how viruses suppress the response through the activity of virus-encoded RNA-binding proteins (reviewed by 2,72,327). RNA silencing—also known as RNA interference (RNAi)—is a critically effective antiviral defense in invertebrates, vertebrates, and plants. Capable of targeting and destroying RNAs from viruses and transposons, RNAi may be a primordial form of innate immunity.⁷⁰ Nodavirus protein B2 functions to suppress RNA silencing that is mounted by the host cell in response to viral RNA replicative intermediates.¹⁹⁶ B2 of FHV was the first discovered example of an RNAi suppressor from an animal virus. B2 enhances FHV multiplication and virus-mediated killing in cultured cells as well as adult *Drosophila* flies.^{103,161,196,340} Demonstrating the effectiveness of the RNAi response in insects, mutant flies with defective RNAi components are more susceptible to killing by FHV.^{103,340} Interestingly, Nodamura virus B2, which grows in both vertebrates and invertebrates, can suppress the RNAi response in both.^{196,198}

The anti-RNAi function of nodavirus B2 is attributed to its sequence-independent dsRNA binding activity.^{2,327} B2 binds to dsRNA (probably dsRNA replicative intermediates generated during virus RNA synthesis) and prevents cleavage by the RNAase III-like endonucleases (Dicer) of the RNAi pathway. Thus, B2 suppresses the generation of small interfering RNAs that are complementary to viral RNAs and used to degrade viral mRNA. The crystal structure of FHV B2 in complex with dsRNA shows B2 as a small four-helix polypeptide that binds as a dimer to a single face of duplex RNA in a sequence-independent manner.⁴⁵ Nodamura virus B2 has a similar protein fold despite its divergent sequence.¹⁷⁴ It is likely that multiple copies of nodavirus B2 bind to viral dsRNAs, protecting them from cleavage by Dicer and blocking incorporation into the RNAi silencing complexes.^{45,269} It will be of interest to ascertain where in the infected cell B2's dsRNA binding activity is localized relative to the nodavirus RNA-replicating spherules on the mitochondrial membranes.

Tetraviridae

Classification of Tetraviruses

The tetraviruses are small RNA viruses that multiply exclusively in lepidopteran insects (moths and butterflies). They contain a single-stranded, positive-sense RNA genome that is packaged into a nonenveloped, icosahedral virion. The family name *Tetraviridae* (“tetra” from Greek *tettares*, meaning “four”) is derived from the virion's T = 4 symmetry, which is the only known T = 4 symmetry among nonenveloped viruses (reviewed in 73,160). A major contribution of these viruses has been their use as models for defining molecular mechanisms of

assembly and maturation of icosahedral viruses. The family is divided into *betatetravirus* and *omegatetravirus* genera, in which *Nudaurelia capensis* β virus (N β V) and *Nudaurelia capensis* ω virus (N ω V) are the prototype species, respectively.¹³³ The tetraviruses *Euprosterna elaeasa* virus and *Thosea asigna* virus are under consideration by the ICTV as members of a new family *Permutotetraviridae* to account for their closer relationship with the RNA viruses of *Birnaviridae*.

Tetravirus Structure

The T = 4 structural features of the tetraviruses (Fig. 73.11) is indicated by cryo-EM reconstructions and X-ray crystallography, including that of N ω V and Providence virus (PrV), a betatetravirus.^{226,297} These studies (reviewed by 296) revealed that the virion contains 240 capsid protein subunits. Twelve chemically identical capsid proteins comprise each triangular face of the virion. The T = 4 capsid arrangement is readily distinguished from the T = 3 symmetry of the smaller nodaviruses that have 60 fewer capsid proteins per particle (Fig. 73.11). Remarkably, the tertiary structures of the capsid proteins of both virus families are very similar. Moreover, the N ω V capsid precursor is cleaved after Asn⁵⁷⁰ near the C terminus in a postassembly mechanism that generates capsid protein β and a smaller peptide γ in a pattern analogous to the required maturation cleavage of nodavirus capsid precursors (see previous discussion). In the nodaviruses, surface exposure of the lipophilic γ peptide can disrupt membranes,^{11,236} suggesting a similar role for tetravirus membrane penetration. The capsid precursor of PrV is also autocatalytically cleaved to produce a larger β capsid protein and a smaller C-terminal γ peptide. However, the PrV γ peptide has a structure and function unlike that of N ω V.²⁹⁷ Instead, the PrV γ peptide contributes to genomic RNA binding within the virion particle, like the nodavirus γ peptide. The striking similarities between the PrV and nodavirus peptides suggest that PrV is more closely related to the T = 3 nodaviruses, indicating that the tetraviruses and nodaviruses may have evolved from a common ancestor.^{160,297}

Tetravirus Genome Organization

The tetravirus RNA genome is either mono- or bipartite. To date, the genomes of four betatetraviruses have been sequenced (reviewed by 73). The single, monopartite RNAs range in size from 5.6 to 6.6 kb, contain a 7-methyl GpppN cap structure at the 5' end, and possess a unique tRNA-like structure at the 3' end.^{1,132} The monopartite genome of betatetravirus N β V¹¹² has two large ORFs. The 5' proximal ORF encodes a 214-kDa, RNA-dependent, replicase-like protein with motifs characteristic of a methyltransferase, nucleotide-binding helicase, and an RNA polymerase. As expected, the RNA replicase-containing polypeptides of the tetraviruses are proteolytically processed.⁷³ The 3' proximal N β V ORF encodes the 66-kDa capsid protein. The capsid ORF overlaps the replicase ORF but uses a different (+1) reading frame. It is therefore likely that the capsid is translated from a 2.5-kb subgenomic RNA¹¹²—*Thosea asigna* virus (TaV) synthesizes a 2.5-kb subgenomic RNA that encodes the capsid protein.²⁶⁴

The omegatetraviruses have a bipartite RNA genome (reviewed by 73). The bipartite genome of omegatetravirus *Helicoverpa armigera* stunt virus (HaSV) contains RNA1 (5,300 bases), which encodes the RNA replicase and smaller proteins, and RNA2 (2,478 bases), which encodes the 71-kDa HaSV

capsid protein and a smaller protein (p17) of unknown function.^{111,132} Typical of the tetraviruses, the HaSV capsid precursor is cleaved near its C terminus to generate an ~62-kDa β protein and a smaller 7-kDa γ peptide during assembly. It is unknown whether the omegatetraviruses co-package both genomic RNAs into a single virion.

Tetravirus Replication, Transmission, and Pathology

Tetraviruses multiply in the cytoplasm of infected cells whereupon crystalline arrays of virus particles accumulate within vesicles.¹³⁹ However, a paucity of permissive cell lines has hindered studies on replicative mechanisms. Such studies have been limited to ectopic expression of individual virus genes in heterologous cell lines.²⁹¹ PrV multiplies (albeit poorly) in lepidopteran cell lines, and newly synthesized genomic and sub-genomic RNAs—as well as virus-encoded capsid proteins—are detected.^{265,297}

The tetraviruses are the only known RNA viruses restricted to insects, specifically those within the order Lepidoptera. Larval infection can be initiated by the ingestion of virus-contaminated foods.¹³¹ Virus multiplication is often restricted to the foregut and midgut cells, even upon injection of infectious virus into the hemolymph of larvae. Virus-mediated killing of midgut cells may account for the stunting pathology associated with HaSV. Susceptible insect larvae exhibit a wide range of pathogenic effects that include rapid death, an extended wasting disease, or a delay in pupation.⁷³ Death occurs within 4 to 7 days, usually accompanied by discoloration, flaccidity, and sometimes liquefaction. Tetravirus infections occur sporadically in natural populations. Thus, ecological aspects of virus spread and the existence of virus reservoirs are poorly understood. Nevertheless, these insect viruses are natural biopesticides that have been observed to control certain insects; several viruses, including *Darna trima* virus and *Thosea asigna* virus have been successfully applied as biopesticides in oil palm plantation settings.¹¹⁰

Dicistroviridae

Classification and Structure

Members of *Dicistroviridae* are small, nonenveloped RNA viruses named for the unusual bicistronic arrangement of their single genomic RNA (Table 73.1). Although these icosahedral insect viruses resemble the vertebrate picornaviruses, they form a taxonomically distinct family.^{30,53,144} The best-characterized dicistrovirus is Cricket paralysis virus (CrPV), the type species within the *Cripavirus* genus of *Dicistroviridae*. Other cripaviruses include the well-studied dipteran *Drosophila* C virus, hemipteran (aphids and leafhoppers) *Rhopalosiphum padi* virus, and hymenopteran (bees and wasps) black queen cell virus. The dicistroviruses, including Israeli acute paralysis virus, have received increased attention recently due to their association with colony collapse disorder in honeybees.³⁰

The physicochemical properties of the cripavirus virion are strikingly similar to those of the vertebrate picornaviruses. The icosahedral virion (< 40 nm diameter, $\rho = 1.35\text{--}1.37$ g/ml) contains four capsid proteins (VP1, VP2, VP3, and VP4) that are arranged in a pseudo T = 3 lattice. The 2.4 Å resolution crystal structure of CrPV shows a picornavirus-like capsid conformation and morphology.³¹⁰ However, CrPV lacks the deep depression (canyon) at the fivefold axis or a VP1 pocket that distinguishes the enteroviruses. Also unlike the picornaviruses, CrPV VP4 residues are located between VP2 and VP3. The proteolytic processing of VP0 \rightarrow VP3 + VP4 appears to be autocatalytic. Thus, cripavirus virion assembly may more closely resemble that of the insect nodaviruses and tetraviruses than the vertebrate picornaviruses.³¹⁰

Genome Organization and Novel Translation Initiation

Dicistroviruses possess a single-stranded, messenger-sense RNA genome about ~9 kb in length. The genome is distinguished by its bicistronic organization of two large ORFs (Fig. 73.12). Upon translation, each ORF produces two different

FIGURE 73.12. Genome organization of the dicistroviruses. The single-stranded RNA genome of the dicistroviruses, including CrPV and DCV, possess two open reading frames (ORF1 and ORF2) separated by an ~200 nucleotide spacer. An internal ribosome entry site (IRES) precedes both ORFs. ORF1 encodes virus replicative functions (helicase, protease, and RNA-dependent RNA polymerase), whereas ORF2 encodes capsid proteins VP0, VP1, and VP2. VP3 and VP4 are generated by processing of precursor VP0.³¹⁰ The small protein VPg and an untranslated region (5' UTR) are located at the 5' end of the genomic RNA. By contrast, the vertebrate picornavirus genome possesses a single ORF; it must therefore produce equimolar levels capsid proteins and replicative functions from the 5' and 3' ends of the genome, respectively.

polyproteins, which are proteolytically processed (reviewed by 30,144). Preceded by a 5' UTR, ORF1 encodes proteins with predicted RNA helicase, picornavirus 3C-like protease, and RNA-dependent RNA polymerase activities. In addition, the N-terminal end of ORF1 of CrPV and DCV encodes novel RNAi suppressors.²²⁹ These suppressors act by distinct mechanisms, but represent a common function encoded by insect viruses, including the nodaviruses. ORF2 is preceded by an intergenic UTR (~200 nucleotides) and encodes the capsid proteins. Thus, unlike the picornaviruses, the capsid proteins and nonstructural replication proteins are encoded by the 3' and 5' halves of the genome, respectively (Fig. 73.12). To date, dicistrovirus replication mechanisms are poorly understood. However, full-length infectious clones, now available for *Rhopalosiphum padi* virus,²⁴⁹ will expedite such studies.

During infection, the dicistrovirus capsid proteins are produced in great excess compared to the nonstructural proteins despite being encoded by the 3' half of the messenger-active genome. Accounting for this difference, an internal ribosome entry site (IRES) regulates translational initiation from each of the two ORFs. Characterized from CrPV, DCV, *Rhopalosiphum padi* virus, and *Plautia stali* intestine virus, these structures are common features of the *Dicistroviridae* and have provided novel insight into mechanisms of translational initiation (reviewed by 144). The use of an IRES avoids the need for a 5' 7-methyl GpppN cap on viral mRNAs, thereby allowing the virus to escape host- or virus-mediated shutdown of cap-dependent protein synthesis during infection. Thus, insects share these antiviral mechanisms with vertebrates. The IRES preceding ORF2 is particularly interesting in that, unlike a typical picornavirus IRES, this dicistrovirus IRES does not require any host initiation factors.¹⁴⁴ Rather, the IRES within the intergenic UTR (Fig. 73.12) assembles an 80S ribosome in the absence of initiator Met-tRNA_i or canonical initiation factors to initiate protein synthesis from the second triplet (GCU), which is positioned within the A site of the ribosome. This novel mechanism for IRES-mediated translation initiation involves a pseudoknot structure within the IRES that substitutes for required interactions between Met-tRNA_i and the P-site initiator codon.¹⁴⁴ Thus, the intergenic dicistrovirus IRES has facilitated important understanding of the molecular mechanisms of IRES function.

Dicistrovirus Prevalence and Transmission

The dicistroviruses are widely disseminated in animal populations (reviewed by 30,144). CrPV was originally isolated from Australian crickets *Teleogryllus oceanicus* and *T. commodus*; its name is derived by its capacity to cause paralysis of the hind limbs of early-instar cricket nymphs. Interestingly, CrPV has one of the widest experimental host ranges of any of the invertebrate viruses and can infect diverse species of multiple insect orders, including those of Diptera, Lepidoptera, Orthoptera, Hymenoptera, and Hemiptera.⁵⁴ Experimental inoculation by injection leads to virus multiplication and death of multiple insect species. CrPV transmission can also occur *per os* through contaminated food sources. In contrast to CrPV, DCV has a more restricted host range. DCV has been isolated from wild or laboratory strains of *Drosophila melanogaster*.⁵⁴ It can be transmitted *per os* to adult flies or larvae and cause death. In addition, DCV is transmitted horizontally between infected and uninfected adults. Thus, the transmission routes and pathology of dicistroviruses among insects is highly variable.

PERSPECTIVES

Considering the abundance and diversity of insect life on earth, it is likely that only a small fraction of the potential viruses that infect insects have been discovered thus far. Nonetheless, studies of the viral pathogens characterized to date have revealed novel mechanisms for virus replication, have identified unique viral genes with functions important in human disease (cancer, neurodegeneration, immunodeficiency), and have provided highly useful applications for biotechnology, insect pest management, and gene therapy. It is fully expected that further studies of the insect viruses will uncover fundamental aspects to host–virus interactions, including novel strategies by which these prolific viruses modify and exploit host processes to enhance multiplication and evade antiviral responses. On the basis that many of these responses are conserved in mammals, such studies will provide important insight into the mechanisms of antiviral defenses and virus pathogenicity in humans. In light of the expansion of the natural range of many arthropod vectors, an important but poorly understood area that will have major impact is the molecular interaction of arboviruses, including dengue virus and West Nile virus, with their insect (mosquito) vectors and how such interactions contribute to transmission to human hosts. In as much as the contributions of insect viruses to basic biology and biotechnology have been enormous and that insect viruses continue to plague humankind, there is a critical need for continued studies at the molecular level and adequate funding to support such investigations.

Giardia lamblia Virus
Trichomonas Virus and Host Phenotypic Variation

Prions, retroviruses, double-stranded RNA (dsRNA) viruses, single-stranded RNA (ssRNA) viruses, and double-stranded DNA (dsDNA) viruses have all been found in simple eukaryote hosts, and the experimental advantages of these systems has made some of them the most thoroughly characterized of their classes. This is an overview of these infectious entities and their unique aspects, with some emphasis on recent developments.

All of the viruses, prions, and retrotransposons (or retroviruses) of yeast and fungi have wholly intracellular life cycles. These viruses have forsaken the extracellular route of transmission, being passed from cell to cell either vertically or by cytoplasmic mixing, such as occurs in mating, or in hyphal anastomosis (fusion) of filamentous fungi. They resemble, in this regard, the plant cryptoviruses and the intracisternal A type particles (retroelements) and LINEs (retroposons) of mammals. We have argued that the high frequency of mating and hyphal fusion of fungi in nature makes an extracellular phase dispensable for these viruses. Indeed, many wild *Saccharomyces cerevisiae* carry the RNA viruses,²⁶³ and it is difficult to find strains of *S. cerevisiae* that lack the Ty retrotransposons.³⁹⁰ Nor is the direct cell-to-cell route of infection completely neglected by mammalian viruses—those of the herpes group and human immunodeficiency virus being prime examples.

Recently, sequences of many yeast genomes have revealed occasional (diverged) copies of the yeast L-A viral and M₂ killer toxin genomes.^{136,350} Interestingly, the integrated viral sequences from distantly related yeasts were less diverged than their hosts, indicating horizontal transfer.³⁵⁰ The means by which this transfer occurs is not yet clear.

The largely intracellular mode of transmission means that these viruses must balance the need to spread and propagate against consideration for the viability of their host. This is clearly seen in the Ty elements, which tend to target sites that can tolerate an insertion. The Ty elements, particularly Ty3, regulate their transcription such that most transposition

occurs on mating. This design optimizes the chances of infecting the potentially unoccupied genome of the mating partner. The copy numbers of several of the RNA replicons (L-A dsRNA, L-BC dsRNA, and 20S RNA) are repressed by the host Ski proteins acting in translation,^{242,294,321,388} messenger RNA (mRNA) stability¹⁸⁵ and positive strand stability.^{139a,b} Furthermore, the fact that most of these elements are widespread means that the hosts have been selected for the ability to protect themselves. Thus, the host blocks Ty1 retrotransposition at several levels: translation, virus particle and DNA stability, structure of the chromatin target, and by antisense RNA.^{26,75,180,195,224,230,245,286}

Most of the viruses and prions discussed in this chapter can best be viewed as selfish RNA or DNA (or selfish protein); however, the killer satellite dsRNAs clearly benefit their hosts (and promote the L-A helper virus) by allowing them to kill competitors. The [Het-s] prion of *Podospora* is unique among prions described to date in being necessary for a normal cellular function—namely, heterokaryon incompatibility.⁷⁹

Yeast and fungal prions have led the way in proving the prion concept, defining the structure of prion amyloids and in relating those structures to prion biology and heritability. Moreover, the study of yeast prions has explored myriad chaperones and other host components affecting prion generation and propagation.

It is striking that many of the viruses and retroelements discussed use some form of ribosomal frameshifting to make a Gag-Pol fusion protein. This is not surprising for the retroelements but was not expected for the dsRNA genomes. Ribosomal frameshifting (in contrast to splicing or RNA editing) provides a mechanism for viruses whose mRNA is their genome to obtain two proteins with overlapping sequence from one mRNA without producing mutant genomes.¹⁸³ Other translational tricks used include read-through of stop codons and internal ribosome entry.

The use of *S. cerevisiae* as a model host for viruses of plants and insects promises to facilitate the understanding of these viruses^{187,261,285} but will not be dealt with here. Surprisingly, a mammalian defense against retroviruses—the APOBEC3 cytidine deaminases that are preferentially incorporated into retrovirions—are also incorporated into Ty1 particles and block retrotransposition by deaminating the viral genome.¹¹²

DOUBLE-STRANDED RNA VIRUSES

Fungal dsRNA viruses were first detected in 1948 as “La France” disease of cultivated mushrooms in Pennsylvania, and its study led to the first description of fungal viruses in 1962. The antiviral agents helenine and statolon, discovered in *Penicillium* in the 1950s, later proved to be fungal virus dsRNA that was inducing interferon production (reviewed in 45).

The dsRNA viruses are found in many fungal species (Table 74.1) and include the single-segment *Totiviridae*, the oligosegmented *Partitiviridae*, the potyvirus-like *Hypoviridae* that limit the virulence for chestnut trees of the chestnut blight fungus *Cryphonectria parasitica*, and reoviruses of the same species.

L-A Virus of *Saccharomyces cerevisiae*, Type Species of the *Totiviridae*

Some strains of *S. cerevisiae* secrete a protein toxin that is lethal to other strains but to which they are themselves immune²³⁷ (Fig. 74.1). This killer character of some strains is inherited as a non-Mendelian genetic element, and its study led to the discovery of the L-A dsRNA virus and its satellites M₁, M₂, M₂₈, and so on, each M encoding a different toxin-immunity specificity.

L-A Virion Structure

The icosahedral structures of L-A and the *Ustilago* virus P4 are unusual in that they combine T = 1 symmetry with 120 coat protein molecules per particle^{58,131,262} (Fig. 74.2). This same symmetry has been found in the cores of all other dsRNA viruses examined, including reovirus, rotavirus, bluetongue virus, aquareovirus, and bacteriophage ϕ 6 (see Chapters 44, 45, and 75). Because sequence data suggest that different dsRNA viruses each arose independently from different ssRNA viruses,²¹³ rather than one being descended from each other, their common structure suggests that there is something about this structure that is well adapted to the intraviral replication pattern of dsRNA viruses.

The combination of 120 subunits and T = 1 icosahedral symmetry implies that individual coat protein monomers can be in either of two environments. This expectation has been verified as subtly different morphology of the nonequivalent Gag protomers²⁶² (see Fig. 74.2). The packing of the dsRNA within the particles is less dense than is typical for dsDNA viruses, possibly reflecting the fact (see later discussion) that in both replication and transcription, the genome must translocate sequentially past the RNA-dependent RNA polymerase immobilized on the particle wall, and this requires more space than is required by the static DNA genomes.⁵⁰ The L-A virions also have 10- to 15-Å pores, which allow entry of nucleotides and exit of positive-strand transcripts but do not allow the dsRNA genome to exit or degradative enzymes to enter.²⁶² A trench on the outer virion surface contains His154 of Gag, the site of the mRNA decapping activity, and several nearby residues essential for this activity have been identified.³⁴⁸

L-A Genome Structure

The L-A positive strand has two overlapping open reading frames (ORFs)¹⁸³ (Fig. 74.3A). They are *gag*, encoding the 76-kd major coat protein, and *pol*, encoding the 100-kd Pol domain of the Gag-Pol fusion protein.^{143,183} The *pol* ORF includes the consensus amino acid sequence patterns typical of viral RNA-dependent RNA polymerases. Three *in vitro* ssRNA binding domains have also been localized to Pol,^{143,291,292} the central one cryptic unless an adjacent inhibitory region is deleted (see Fig. 74.3A). Pol residues 67 to 213 are necessary for packaging of the viral positive strands.^{141,292} Neither 5' cap structure nor 3' poly(A) has been found on either strand of genomic L-A dsRNA or M₁ dsRNA⁴³; however, there is, at each 3' end, an uncoded base that can be either A or G.³⁸

The M dsRNAs each encode, in their 5' portion, a prepro-toxin protein^{33,99,233,320} (see Fig. 74.3B). The M₁ positive strand has an internal encoded polyA region whose length shows frequent clonal variation, presumably owing to transcriptase stuttering,³³⁴ and a substantial 3' region that encodes no protein but contains essential *cis* sites.^{127,139,158,311,328} Sites on the L-A

TABLE 74.1 Double-Stranded RNA, Single-Stranded RNA, and Double-Stranded DNA Viruses of Simple Eukaryotes

Virus	Host species	kb	Features (reference)
dsRNA viruses			
<i>Totiviridae</i>			One segment, Gag-Pol, T = 1 icosahedral
L-A	<i>Saccharomyces cerevisiae</i>	4.6	Type species
M ₁ , M ₂ , M ₂₈	<i>S. cerevisiae</i>	1.6–1.8	Satellites of L-A; killer toxins (378)
L-BC	<i>S. cerevisiae</i>	4.6	(378)
Hv190S	<i>Helminthosporium victoriae</i>	4.5	Coat protein phosphorylated; internal translation initiation (159)
P1-H, P4-H, P6-H	<i>Ustilago maydis</i>	2.6–6.1	Killer toxin (212)
Af V-S, AfV-F	<i>Aspergillus foetidus</i>		(44)
AnV-S, AnV-S	<i>Aspergillus niger</i>		(44)
YIV	<i>Yarrowia lipolytica</i>		(165)
LRV	<i>Leishmania braziliensis</i>	5.28	(340)
GLV	<i>Giardia lamblia</i>	6.27	Infectious; transformation (372)
TVV	<i>Trichomonas vaginalis</i>	4.6	(200)
	<i>Zygosaccharomyces bailii</i>	4.0, 2.9, 1.9	Killer toxin (287)
	<i>Eimeria</i>		(324)
	<i>Blastomyces dermatitidis</i>	5.0	(211)
<i>Partitiviridae</i>			Two segments
	<i>Atkinsonella hypoxylon</i>	2.2, 2.1, 1.8	(271)
	<i>Penicillium chrysogenum</i>		(45)
	<i>Penicillium stoloniferum</i>		(45)
	<i>Agaricus bisporus</i>		(45)
	<i>Rhizoctonia solani</i>	2.2, 2.0	(135)
<i>Hypoviridae</i>			
CHV1-EP713	<i>Cryphonectria parasitica</i>		Hypovirulence-associated virus
<i>Reoviridae</i>			
	<i>C. parasitica</i>	1–3 (11 segments)	Hypovirulence-associated virus (174)
ssRNA replicons			
<i>Narnaviridae</i>			Naked RNA viruses
20S RNA	<i>S. cerevisiae</i>	2.5	(129)
23S RNA	<i>S. cerevisiae</i>	2.9	(126)
NB631 RNA	<i>C. parasitica</i>	2.7	(345)
dsDNA viruses			
PBCV-1 and many others	<i>Chlorella</i>	333	(365)

dsRNA, double-stranded RNA; ssRNA, single-stranded RNA; dsDNA, double-stranded DNA; PBCV, *Paramecium bursaria Chlorella* virus.

and M₁ positive strands necessary for packaging and negative-strand synthesis have been determined (see later discussion and Fig. 74.3), and some limits have been set on the possible transcription signals.

Stages in the Replication Cycle

The L-A replication cycle and the closely related cycle of its satellites are shown in Figure 74.4.^{131,140} L-A dsRNA-containing viral particles synthesize positive ssRNA in a conservative reaction,^{140,173} and these new positive strands are then extruded from the particle.¹⁴⁰ There, they serve as mRNA for the production of the Gag and the Gag-Pol fusion proteins. These proteins then assemble with a viral positive strand to form new particles. The newly assembled viral particles carry out the synthesis of negative strands on the positive-strand template to form dsRNA and complete the cycle.¹⁴⁰

In addition to their appropriating viral proteins from L-A, the replication cycle of the satellite dsRNAs, M₁, S (deletion

mutants of M₁), and X (a 530 base pair [bp] deletion mutant of L-A) are similar to that of L-A itself except that they replicate more than once within the viral particle until it is full (see Fig. 74.4). Only a single positive ssRNA is packaged per particle,¹³⁹ thus L-A and M are separately encapsidated. Because the particle capacity is determined by the structure of Gag to be sufficient to accommodate one full-length L-A dsRNA molecule, positive-strand transcripts of the smaller M and X dsRNAs are often retained within the particles, where they are converted to new dsRNA molecules. All new positive strands are extruded from the full particles.^{130,131} This headful replication mechanism contrasts with the headful packaging mechanism of many DNA bacteriophage.^{130,131} This implies that extrusion of the transcripts is a mechanical consequence of the head being full rather than an active process. Both positive and negative strands are synthesized within the viral particles, but at different points in the cycle; therefore, the replication is conservative, intraviral, and asynchronous, and it fills the capsid (headful mechanism).

FIGURE 74.1. The killer phenomenon of *Saccharomyces cerevisiae*.

A sensitive strain of yeast was spread as a lawn, and streaks of a killer strain (**above**) or a nonkiller strain (**below**) were applied. After 2 days of incubation, the lawn of the sensitive strain has not grown in a zone around the killer strain. The secreted protein killer toxin, and immunity to the toxin, are encoded by M_1 , a satellite double-stranded RNA (dsRNA) of the L-A dsRNA virus.

Transcription Reaction (Positive-Strand Synthesis)

As in the *Reoviridae*, the transcription reaction for L-A is conservative,^{140,391} resulting in the overall process of viral replication being conservative.²⁶⁹ However, in *Aspergillus foetidus* slow virus and *Penicillium stoloniferum* slow virus,⁴⁶ dsRNA transcription is semiconservative. The difference between conservative and semiconservative reactions concerns whether or not there is re-pairing of the template negative strand with the parental positive strand that was (in either case) displaced during the synthesis.

Treatment of L-A virus particles with very low ionic strength results in their rupture and release of the dsRNA. These opened empty particles can be reisolated free of RNA and carry out a dsRNA template-dependent reaction that is, like the *in vivo* reaction, conservative.¹⁴⁵ This reaction is highly template specific, using only L-A, M, and X dsRNAs (all physiologic templates), but not L-BC, p6, or rotavirus dsRNAs.¹⁴⁵ Because X dsRNA retains only 25 bp of the end of L-A from which the transcription reaction starts,¹³⁰ the signal recognized by the transcriptase is most likely within this region, perhaps within the terminal 6 bp that are in common among L-A, M_1 , and M_2 .^{169,356} The template-dependent transcription reaction requires very high concentrations of polyethylene glycol (20%), suggesting that the transcriptase has a low affinity for the dsRNA template.¹⁴⁵ Because the dsRNA is normally formed within and stays inside the viral particles, the RNA polymerase sees a very high effective concentration and need not have a particularly high affinity.

Translation

The translation apparatus is a prime battleground for the fight between an RNA virus and its host. For example, interferon acts primarily by blocking viral translation. Picornaviruses cleave a cap-binding protein inactivating host translation

FIGURE 74.2. L-A double-stranded RNA virus capsid at 3.4-Å resolution from X-ray crystallography.^{262,348} **A:** Overall organization of the L-A capsid. Identical subunits occupy two different environments, with “A” subunits (blue) contacting the two- and five-fold axes and “B” subunits contacting the threefold axes. **B:** A single A subunit is shown with the trench on the outside surface including His154, the site of the decapping activity.

FIGURE 74.3. A: Sites and encoded proteins of the L-A positive strand. The sites responsible for -1 ribosomal frameshifting, positive single-stranded RNA packaging, and replication are shown. The pseudoknot makes the ribosome pause over the slippery site, where the transfer RNAs can unpair from the messenger RNA and re-pair in the -1 frame with correct base pairing of the nonwobble bases. Functional domains in the Pol region are also indicated. 7mGp indicates the cap-binding site at His154 of Gag. **B:** Coding and *cis* sites of M1 positive strand. The analogous and homologous processing of the K1 preprotoxin encoded by M1 is compared to that of preproinsulin.

FIGURE 74.4. Replication cycles of L-A virus and its satellite double-stranded RNAs (dsRNAs), M and X. The packaging region of the Pol domain of Gag-Pol binds to the packaging site of positive strands as the Gag domain associates with other Gag molecules. This ensures packaging of viral positive strands.^{141,143} L-A particles have only one dsRNA molecule per particle. However, the smaller M or X dsRNAs replicate within the viral coat until they fill the head.^{130,131}

(Chapter 16), and influenza virus steals caps from cellular mRNAs (Chapter 40). RNAi also blocks translation of target mRNAs or promotes their degradation. Studies of the L-A virus and its satellites likewise suggest that translation of viral proteins is a critical event determining the balance between virus and host.

ribosomal frameshifting

The *gag* and *pol* ORFs of L-A overlap by 130 nucleotides, and the Pol protein is expressed only as a fusion protein with the major coat protein, Gag^{143,183} (see Fig. 74.3A). The mechanism of formation of this Gag-Pol fusion protein is a -1 ribosomal frameshift,¹⁰¹ very similar to those described in Rous sarcoma virus, many mammalian retroviruses, coronaviruses, and several plant viruses (184; reviewed in 15,40).

The frequency of -1 ribosomal frameshifts is determined by the “slippery site,” a sequence of the form X XXY YYZ, where the *gag* reading frame is shown, and by a downstream pseudoknot (see Fig. 74.3A). The slippery site allows the transfer RNAs (tRNAs) reading XXY and YYZ to move back one base on the mRNA and still have their nonwobble bases correctly paired.¹⁸⁴ X can be any base, although Y can be only A or U, probably because the frequency with which unpairing of the tRNAs from the 0 frame codons (XXY and YYZ) is also

important, and because A site pairing is stronger than P site pairing.^{39,101} Z can be any base but G, suggesting that specific tRNAs are more able to frameshift than others.⁵² The RNA pseudoknot, just downstream of the slippery site, slows ribosomal movement at this point.^{39,101} The location of this secondary structure is particularly critical,³⁹ and a pseudoknot is far more effective in promoting frameshifting than a simple stem loop of the same overall melting energy. The pseudoknot, more than the simple stem loop, should halt melting of the stem at a unique point because the rotation of the stem is limited by the downstream stem. This precisely positions the ribosome with the slippery site in the A and P sites.²⁸²

The efficiency of -1 frameshifting, and thus the ratio of Gag-Pol fusion protein to Gag protein produced, is critical for viral propagation,¹⁰⁴ as is the efficiency of +1 frameshifting for Ty1 retrotransposition frequency (see later discussion). A two-fold change away from L-A’s normal 1.9% efficiency results in failure to propagate the M₁ satellite dsRNA. L-A propagation is less sensitive; however, the antibiotics sparsomycin, which increases ribosomal frameshifting, and anisomycin, which has the opposite effect, can cure L-A.¹⁰² The Gag-Pol to Gag ratio is likely to be important for viral assembly. Excess Gag-Pol (high frameshift efficiency) may result in starting too many particles and winding up with too little Gag to complete any of

them. In contrast, excess Gag might result in particles closing before the packaging domain of Pol has had a chance to find a viral positive strand.¹⁰²

Host genes affecting the efficiency of -1 frameshifting are referred to as *MOF* (maintenance of frame).^{104,105} The differential effects of specific host mutations on frameshifting at specific slippery sites suggests that drugs similarly affecting frameshifting might target specific viruses.¹⁰⁵ *MOF9* is the 5S ribosomal RNA (rRNA), showing a role for this 60S subunit component in maintenance of reading frame.¹⁰³ *MOF6* is *RPD3* encoding a histone deacetylase; the *mof6-1* allele affects rRNA processing in such a way that ribosomal frameshifting is increased.²⁵⁴ Ribosomal frameshifting is also used in some mammalian genes, such as *Edr* (embryonal carcinoma differentiation regulated),³³¹ and various yeast genes affected by a frameshifting site have been identified.^{23,168} Whereas viral ribosomal frameshifting produces two viral proteins in a desired ratio, that of yeast cellular genes increases mRNA instability by diverting translating ribosomes to termination codons in another frame and inducing nonsense-mediated decay.²³

The 190S virus of *Helminthosporium victoriae* (Hv190SV) is a totivirus that does not make a coat protein–RNA polymerase fusion protein and does not use ribosomal frameshifting in its gene expression. Instead, the termination codon for the coat protein overlaps with the initiation codon for the RNA polymerase, the sequence being...GGA CAA **TG** AGT G....¹⁸¹ The RNA polymerase is detected only as a separate protein, and it is apparently translated by the occasional reinitiation of ribosomes that have just terminated at the end of the coat protein part of the mRNA.

60S SUBUNITS—CRITICAL TO VIRAL PROPAGATION

Mutations in any of 20 chromosomal genes (called *MAK* [maintenance of killer]) that result in diminished levels of free 60S ribosomal subunits also produce loss of M dsRNA and decreased copy number of L-A dsRNA.^{116,272} Mutations diminishing the supply of free 40S subunits generally had no such effect.²⁷² The deficiency of 60S subunits results in selectively decreased rates of translation of mRNAs which, like L-A mRNA, lack 3' poly(A).¹¹⁶ These *mak* mutations are suppressed by the *ski* mutations that derepress translation of non-poly(A) mRNAs.^{242,358}

GAG DECAPPING ACTIVITY—NECESSARY FOR M EXPRESSION

The *SKI1/XRN1* gene was first detected as superkiller mutants,³⁵⁷ and overexpression of Ski1p can cure the L-A virus.¹²⁸ The L-A and L-BC Gag proteins each covalently bind the 5' cap from any RNA *in vitro*.²⁷ L-A Gag covalently attaches ^{7m}GMP from the cap to His154 in a reaction that requires only Mg²⁺.²⁸ Modification of His154 destroys Gag's ability to covalently bind cap, resulting in loss of killer toxin expression from M₁ without affecting propagation of the M₁ satellite virus.²⁸ Mutation of the *SKI1/XRN1* gene encoding the 5' to 3' exoribonuclease, specific for uncapped RNAs and responsible for the major mRNA decay pathway,¹⁷⁹ results in restoration of expression of killer toxin despite mutation of His154 of Gag.²⁴² It has been proposed that the virus decaps cellular mRNAs to decoy the Ski1p exoribonuclease from degrading the capless viral mRNA.²⁴² However, recent evidence shows that L-A virions can transfer the cap structure to nascent L-A mRNAs.^{139a,b}

SKI ANTIVIRAL SYSTEM BLOCKS TRANSLATION OF VIRAL [NON-POLY(A)] MESSENGER RNA

The sole essential function of four of the *SKI* genes of *S. cerevisiae* is the repression of viral copy number, particularly control of M.^{24,25,294,335,358} The Ski proteins repress three unrelated viral systems: L-A and its satellites, L-BC (a dsRNA virus), and the ssRNA replicon referred to as 20S RNA.^{14,246,358} Detailed studies of *SKI2* suggested that the system acts by limiting translation of viral mRNA.^{242,388} Because none of these cytoplasmic replicons has either 5' caps or 3' poly(A) structures, it was speculated that the *SKI* system recognized the absence of one or both of these structures.³⁸⁸ That *SKI2* also represses translation of RNA polymerase I transcripts, probably lacking cap and/or poly(A), supports this idea.³⁸⁸

Electroporation of mRNAs into spheroplasts shows that the Ski2, Ski3, Ski6, Ski7, and Ski8 proteins inhibit the translation of mRNA specifically if it lacks a 3' poly(A) structure.^{24,25,242} Kinetic studies indicate that both the initial rates and the duration of translation are affected by the Ski proteins. The Ski proteins also affect a minor mRNA degradation pathway.¹⁸⁵

Among the *SKI* genes, only *SKI6* is essential for growth in the absence of M dsRNA.^{24,25,290,335,388} Ski2p has helicase motifs, a glycine-arginine-rich domain, and it is highly homologous to two mammalian genes.³⁸⁸ Ski3p has the TPR amino acid repeat pattern,²⁹⁰ whereas Ski8p has a different sequence repeat first identified in β -transducin.³³⁵ Ski2p, Ski3p, and Ski8p form a cytoplasmic complex.⁴¹ Ski6p is homologous to RNase PH, a tRNA-processing enzyme,²⁴ and it is part of a nuclear complex of exoribonucleases that has a role in rRNA processing.²⁵⁶ The *ski6* mutants produce abnormal 60S ribosomal subunits and show abnormalities in processing of 5.8S rRNA.²⁴ Ski7p has homology to EF1- α , an elongation factor, suggesting that it is involved in the translation process.²⁵

SLH1 is a yeast homolog of *SKI2*, and like *ski2 Δ* , *slh1 Δ* has elevated L-A copy number.²⁴¹ The *ski2 Δ slh1 Δ* double mutants show dramatically increased L-A, L-BC, and M₁ dsRNA copy numbers but grow normally in the absence of the L-A and M₁ viruses.³²¹ Remarkably, the *ski2 Δ slh1 Δ* cells show the same *in vivo* translation kinetics of non-poly(A) mRNA as they do for poly(A)+ mRNA, despite the presence of normal amounts of competing poly(A)+ mRNA.³²¹ Thus, the translation apparatus is indifferent to the 3' poly(A) structure except for the action of the Ski proteins and Slh1p. This suggests that one role of the eukaryote 3' poly(A), like that of Ski2p and Slh1p, is to allow cells to distinguish their own mRNAs from those of invading viral genomes.

Posttranslational Modification

KEX1 AND KEX2 PROTEASES AND DISCOVERY OF PROHORMONE PROTEASES

The *kex1* and *kex2* mutants were first isolated because of their inability to produce the "killer" toxin encoded by the M₁ satellite dsRNA (*KEX*, from killer expression).³⁸⁴ The *kex2* mutants have a defect in mating specific to cells of the α mating type, and *kex2/kex2* homozygous diploids are defective for sporulation.²²⁶ The α -specific mating defect was partially explained by the finding that the cells failed to secrete the α pheromone,²²⁶ a peptide that prepares cells of the opposite (a) mating type for mating by arresting them in the G1 phase of the cell cycle. The failure to secrete killer toxin and a pheromone was explained

by the finding that *KEX2* encodes a protease that cleaves C-terminal to pairs of basic amino acid residues,¹⁹⁰ and that *KEX1* encodes a carboxypeptidase that can remove the pair of basic amino acids.^{76,106} These were the cleavages needed to convert the toxin and α pheromone proproteins to their mature forms (see Fig. 74.3B).

The specificities of the Kex proteases are the same as those needed to process preproinsulin (see Fig. 74.3B), pre-pro-opiomelanocortin, and other mammalian prohormones; however, the enzymes responsible for these maturation cleavages had been elusive. Several genes and enzymes with homology to Kex2p were identified, and they are indeed involved in these prohormone processing steps (reviewed in 301).

The Kex2p-homologous enzymes are also involved in the proteolytic processing of some mammalian viral proteins. Mutant CHO cells resistant to Sindbis virus and Newcastle disease virus were made sensitive by expression of the Kex2p homolog, mouse furin, or by expression of Kex2p itself.²⁵⁷

N-ACETYLATION OF GAG BY MAK3P—NECESSARY FOR ASSEMBLY

MAK3, *MAK10*, and *MAK31* are necessary for the propagation of the L-A dsRNA virus. Mak3p is homologous to *N*-acetyltransferases,³⁵⁴ and the *N*-acetylation of the L-A Gag protein is lost in a *mak3* mutant host, resulting in failure of viral assembly.³⁵⁵ Mak3p recognizes the N-terminal four amino acid residues of Gag.³⁵³ Like L-A, the major coat proteins of Rous sarcoma virus, tobacco mosaic virus, turnip yellow mosaic virus, alfalfa mosaic virus, and potato X virus are N-terminally acetylated.

The only three host proteins known to be necessary for L-A propagation, Mak3p, Mak10p, and Mak31p,³⁸¹ form a complex,²⁹⁵ indicating that Mak10p and Mak31p are also involved in *N*-acetylation of the coat protein. In addition to its action on Gag, the Mak3p acetylase also is responsible for modification of the $\alpha 5$ and $\alpha 6$ proteasome subunits,²⁰⁵ and both *mak3* and *mak10* mutants grow poorly on ethanol or glycerol.^{100,225,354}

Viral Assembly

The headful replication mechanism implies that the coat protein determines the structure of the head, not the genome. This is typical of isometric viruses. In fact, expression of the Gag protein alone produces empty particles that are morphologically indistinguishable from normal L-A virions.¹⁴¹ Normal L-A particles have a $T = 1$ icosahedral structure with an asymmetric unit consisting of a dimer of Gag (262; see preceding discussion). Each particle has only one or two Gag-Pol fusion proteins (perhaps as a dimer). The requirement for the Mak3p-catalyzed *N*-acetylation of Gag for assembly suggests that the Mak3/10/31 complex is involved in this process.

The existence of a Gag-Pol fusion protein, the ssRNA binding activity of its Pol domain, and the fact that positive ssRNA is the species encapsidated to form new viral particles led to a model of assembly and packaging that has been supported by subsequent findings¹⁴³ (see Fig. 74.4). The Pol domain of the Gag-Pol fusion protein recognizes and binds to a packaging site on the viral positive strands. Then (or concomitantly), the Gag domain of the fusion protein associates with the free Gag protein. This leads to encapsidation of a single

positive strand per particle if there is only one Gag-Pol fusion protein (or one dimer) per particle.

In vivo, Pol residues 67 to 213 of the Gag-Pol fusion protein are necessary for packaging of positive strands but not for assembly of morphologically normal viral particles.^{141,292} One of the three ssRNA binding domains of Pol is located within this region and is necessary for the packaging²⁹² (see Fig. 74.3A).

The *packaging site* recognized is an internal stem-loop sequence about 400 nucleotides from the 3' end with an A residue bulging from the 5' side of the stem¹³⁹ (see Fig. 74.3A). Binding requires the stem structure but not the sequence of the stem. In contrast, the sequence of the loop is important. The protruding A residue must be present and must be an A.¹³⁹ A similar site, similarly located on the M₁ positive strand, was found¹³⁹ by examining the predicted folded structure of the M₁ sequence,¹⁵⁸ and another was found by studying sequences involved in exclusion of M₁.³²⁸ Either the L-A or M₁ stem loops are sufficient for binding; however, the addition of 10 bp from the 5' side of either one improves the binding substantially.^{139,328} Both the L-A and M₁ sites contain direct repeat sequences whose significance has not yet been determined. A site with the same structure has also been found in a similar location in the M₂₈ satellite dsRNA.³¹⁹

The L-A and M₁ sites can each serve as a portable packaging signal *in vivo*, directing packaging of heterologous transcripts by L-A virus or by proteins produced from the L-A complementary DNA (cDNA) clone.^{139,141} The heterologous transcripts were packaged alone in viral particles, confirming the prediction of the headful replication model that a single positive strand is initially packaged per particle.

Replication (Negative-Strand Synthesis)

Newly assembled viral particles contain an L-A positive strand and are capable of converting it to the dsRNA form when supplied with nucleoside triphosphates.¹⁴⁰ The particles formed in this reaction have all the properties of mature L-A particles and can carry out the transcription reaction.

The opened empty particles (see earlier discussion), when supplied with viral positive strands, Mg²⁺, nucleoside triphosphates, and a low concentration of polyethylene glycol, carry out negative-strand synthesis to form dsRNA.¹⁴⁶ Only L-A, M, or X positive-strand templates are active in this reaction, supporting the notion that it accurately reflects the *in vivo* reaction.

A maximally active template requires both sequences at the 3' end of the L-A (or X) positive strand and internal sequences (the internal replication enhancer) overlapping the packaging signal.¹³⁰ The 3' end of L-A positive strands has a stem loop whose structure is necessary for template activity. Whereas the sequence of the loop and that of the 3' terminal 4 nucleotides are important, that of the stem is not. Despite the requirements for these structures and sequences in the context of L-A, the 3' terminal 33 nucleotides of M₁'s positive strand can substitute for the L-A 3' end, although there is little or no similarity between the two sequences¹³⁰ (see Fig. 74.3). The internal replication enhancer and the 3' end site must be bound together for optimal template activity in the replication reaction.¹⁴⁴ However, they need not be covalently attached and can simply be hydrogen bonded. This suggests that the RNA polymerase binds first to the internal site and is thus brought close to the 3' end site where polymerization is to begin.

Because the RNA-dependent RNA polymerase consensus domains defined by Kamer and Argos¹⁹⁴ have since been found in essentially all positive ssRNA and dsRNA viruses examined, the detailed mutagenesis of the most highly conserved of these regions was carried out using the L-A cDNA clone.²⁹³ This has defined the extent of the domains necessary for the propagation of the M₁ satellite dsRNA. Interestingly, homologous regions from reovirus or Sindbis virus RNA polymerases could partially substitute for that of L-A.²⁹³

Other Factors Affecting L-A, M, and L-BC Replication

Mutation of either *POR1*, encoding the major mitochondrial outer membrane porin, or *NUC1*, encoding the major mitochondrial nuclease, results in derepression of L-A copy number.^{100,232} A similar effect results from mutation of *scs1/lbc2*,¹⁵⁶ encoding a subunit of serine palmitoyltransferase. *MKT1* is necessary for M₂ propagation but not for M₁.³⁷⁹ Several natural variants of L-A have been described based on their interactions with *MKT1*, M₂ dsRNA, and *mak* mutations affecting levels of free 60S ribosomal subunits; however, the mechanisms of these interactions have not yet been determined (reviewed in 381).

Partitiviridae

The *Partitiviridae* have a bipartite genome with the two segments separately encapsidated in particles containing the proteins encoded by both segments.⁴⁴ This group includes viruses of the filamentous fungi *Penicillium* and *Aspergillus* and the mushroom *Agaricus*, as well as many other fungi. It

also includes a large group of plant cryptoviruses,^{29,266} whose genome is dsRNA and whose biology is much like that of the systems discussed in detail here.

Strain 2H of *Atkinsonella hypoxylon* has three dsRNA segments of 2,180, 2,135, and 1,790 nucleotides. Segment 1 encodes an RNA-dependent RNA polymerase, and segment 2 encodes a 74-kd protein that may be the major coat protein.²⁷¹ The third segment does not appear to encode a protein.²⁷¹

SINGLE-STRANDED RNA REPLICONS

Viruses Reducing Virulence of *Cryphonectria parasitica*

The American chestnut tree was devastated by the accidental introduction, in 1905, of the pathogenic fungus *C. parasitica*, along with an oriental variety of the chestnut tree (reviewed in 175,270). The fungus virtually eliminated the upper parts of the chestnut trees in the eastern United States, although the root systems were not killed and shoots continued to emerge, only to have their growth limited by the reattack of the fungus. *C. parasitica* had a similar effect in Europe; however, in the 1950s, the emergence of fungal strains in Italy with markedly reduced virulence to the trees was noted. These “hypovirulent” strains (Fig. 74.5), later also found in Michigan, could transmit their hypovirulence by hyphal anastomosis to virulent strains, and this was used successfully for the biologic control of chestnut blight in Europe. Hypovirulent strains also show decreased asexual spore formation, decreased production of

Chestnut tree infected with *Cryphonectria parasitica*:

not carrying hypovirus

carrying hypovirus

FIGURE 74.5. Virulent (uninfected, **right**) and hypovirulent (virus-infected, **left**) *Cryphonectria parasitica* (chestnut blight fungus) inoculated into chestnut trees. Infection of the fungus by any of several hypoviruses attenuates its virulence toward the trees. (Courtesy of Dr. Donald Nuss.)

authors to propose that the advantage of having a killer system resulted in loss of the RNAi system.^{109a}

Virus Induction of Hypovirulence

CHV1-EP713 has very specific effects on certain genes. For example, the laccase gene encodes a phenol oxidase believed to be involved in pathogenesis. Transcription of the laccase gene is repressed by CHV1-EP713 infection,^{67,296} an effect that can be produced by expression of just the p29 protease encoded by part of ORF6.⁶⁸ Although p29 is sufficient to alter fungal phenotypes, it is neither necessary nor sufficient to cause hypovirulence.⁸² Deletion of p29 from the virus results in decreased induction of the hypovirulence-associated traits but no decrease in hypovirulence itself. The symptom-determining domain of p29 has now been localized to the interval Phe25 to Gln73 of p29.³⁴⁴ The effect of CHV1-EP713 on laccase appears to be transmitted by an influence on the inositol triphosphate–calcium signal transduction system of the fungus, possibly explaining the multiple phenotypic effects of hypovirulence.²²² The CHV1-EP713 hypovirus also up-regulates the cppk1 protein kinase and prevents activation of the HOG pathway mitogen-activated protein (MAP) kinases resulting in hypersensitivity to osmotic stress.^{204,273}

Cryparin, a hydrophobic cell surface protein, is also reduced in hypovirulent strains, an effect mediated at transcription.⁴⁰³ Another gene, *Vir2*, was isolated based on its decreased transcription in a hypovirulent strain. Although no effect was seen on virulence itself, deletion of this gene partially mimics some of the hypovirulent-associated traits, with decreased asexual sporulation and fruiting body formation and impaired mating ability.⁴⁰² The hypovirulence-associated traits are thus caused by specific effects of viral gene products, rather than by the presence of a replicating dsRNA.

G protein signaling is also implicated in the induction of hypovirulence by CHV1-EP713. Hypovirus infection leads to decreased expression of the host Gia (an inhibitory subunit of G protein) and a concomitant increase in cAMP levels.^{56,66} Moreover, disruption of *cpg-1*, the gene for Gia, results (in an uninfected strain) in elevated cAMP levels, total loss of virulence, and the development of the same associated phenotypes seen on virus-induced hypovirulence.¹⁵⁰

Infectious Complementary DNA Clones and Biological Control of Chestnut Blight

Introduction of complete cDNA clones of L-dsRNA under control of the *C. parasitica* glyceraldehyde-3-phosphate dehydrogenase promoter resulted in both a complete hypovirulence phenotype of the fungus and the launching of the RNA replicon in a form transmissible to other strains.⁶⁹ In addition to its usefulness in studying the mechanism of the effects of CHV1-EP713 dsRNA on the cell, this infectious cDNA clone method is an important advance in attempts to control chestnut blight. Although artificial inoculation of trees with hypovirulent fungal strains in Europe resulted in spread of the hypovirulence dsRNAs to virulent strains and control of the blight, this approach has not succeeded in the United States. CHV RNA spreads by fusion between fungal cells, a process called *hyphal anastomosis*, but not by sexual crosses.⁷ Hyphal anastomosis requires that strains have identical alleles at several different loci determining compatibility. The number of compatibility groups is apparently much greater in the United

States, limiting the spread of the hypovirulence dsRNA. In fact, limiting the spread of debilitating viruses is the presumed function of this heterokaryon incompatibility system (see the section, [Het-s]—a Prion of *Podospora* Responsible for a Normal Function).

In contrast, infectious cDNA incorporated into the *C. parasitica* genome, while generating dsRNA replicons, will also naturally spread to other mating and vegetative compatibility groups through sexual transmission.^{69,270} It is thus expected to be more effective in the biological control of chestnut blight than the natural virus, and early results support this expectation (reviewed in 270).

Recently, the cDNA clone has also been used to introduce CHV1-EP713 into other plant-pathogenic fungi of the order *Diaporthales*.³¹⁵ Infection produced both phenotypic changes and a decrease of virulence in these heterologous hosts.

Reovirus of *Cryphonectria*

Two strains of *C. parasitica* have been found carrying reovirus-like elements associated with hypovirulence.^{120,277} Strains C18 and 9B21 each have 11 dsRNA segments ranging in size from about 1 to about 3 kb and associated with 60-nm virus particles, unlike the vesicles in which the potyvirus-like *Hypoviridae* are found. These 11 segments are present in equimolar amounts, and transmission studies show that either all or none of the segments are transmitted, suggesting that they are parts of a single viral genome. The C18 and 9B21 genomes are not closely related, and sequencing shows that 9B21 is related to the *Coltivirus* group (e.g., Colorado tick fever virus).³⁴⁵ As has been shown for the L-A dsRNA virus system with the killer trait,¹¹⁹ these reovirus particles can be introduced into *Cryphonectria* spheroplasts and transmit the hypovirulence traits.¹⁷⁴ This system adds new dimensions to the study of both hypovirulence and the *Reoviridae*.

20S RNA and 23S RNA

In 1971, a stable species of RNA, intermediate in size between 18S and 25S rRNAs, dubbed 20S RNA, was found to appear specifically in cells exposed to the condition used to induce meiosis and sporulation—namely, when acetate is supplied as the carbon source in the absence of a nitrogen source.¹⁹³ The ability to produce 20S RNA was then found to be inherited as a non-Mendelian genetic element, distinct from other known elements.¹⁵⁷ It was not connected with meiosis, except that the same culture conditions are used to induce both.¹⁵⁷ 20S RNA was finally proven to be an independent RNA replicon whose copy number is inducible in acetate.²⁴⁶ Its sequence shows that its 2,500 nucleotides encode a single 95-kd protein with some similarities to the RNA-dependent RNA polymerases of RNA phages and RNA viruses.^{247,302} W dsRNA, a minor species inducible by growth at high temperature,³⁷⁷ proved to have the same sequence as 20S RNA.^{247,302} Electron micrographs of purified 20S RNA showed about 50% circular molecules²⁴⁶; however, biochemical experiments indicate that the RNA itself is not circular.³⁰³ The terminal sequences of 20S RNA were shown to be 5'GGGGC GCCCC-OH3',³⁰⁴ suggesting that a circular structure may have been formed by hydrogen bonding.

20S RNA is cytoplasmic and lacks a coat protein³⁸⁷ but is found in a 1:1 complex with its encoded 91-kd RNA polymerase,¹⁵¹ and these complexes synthesize 20S RNA and

its complementary strand.¹⁵² An infectious clone of 20S RNA has now been developed and used to show the importance of terminal nucleotides.¹²⁹ The RNA polymerase binds to three sites on 20S RNA, at the 5' end, the 3' end, and in the middle of the sequence, and all three sites are important for propagation of the genome.¹³⁸ Intermediates in replication are positive and negative single strands, not dsRNA.¹⁴²

T dsRNA was discovered as a minor species of dsRNA easily detected in cells lacking L-A and L-BC, and shown to be like W dsRNA, an independent replicon inducible by growth of cells at high temperature.³⁷⁷ T has the same sequence as 23S ssRNA.¹²⁵ 23S RNA has substantial homology with 20S RNA and likewise appears to encode an RNA-dependent RNA polymerase,¹²⁵ with which it is associated in extracts.¹²⁴ 23S and 20S are closely related independent replicons, much like L-A and L-BC.¹²⁹ An infectious cDNA clone of 23S RNA has been developed and used to study the terminal sequence requirements for replication.¹²⁶

The copy numbers of 20S RNA and 23S RNA are controlled by media conditions, requiring acetate as the carbon source and the absence of a nitrogen source for their 10,000-fold induction.^{124,193,246} Both are also induced by growing cells at 37°C, and at least 20S is repressed by the *SKI* system.^{246,377} The *SKI* effect apparently reflects the absence of 3' poly(A) on 20S mRNA (see earlier discussion).

Cryphonectria parasitica Mitochondrial Replicon NB631 Double-Stranded RNA

Polashock and Hillman²⁸⁴ have described a mitochondrial dsRNA species in *C. parasitica* strain NB631. If one assumes the mitochondrial genetic code (UGA=Trp), then the NB631 dsRNA has a single long ORF that encodes an RNA-dependent RNA polymerase. This RNA polymerase is most closely

related to those of 20S and 23S RNAs, and all are more closely related to RNA phage such as Q β , than to RNA viruses of higher organisms.^{283,302} The degree of similarity is such that these elements must be very close relatives. Nevertheless, 20S RNA and 23S RNA are primarily ssRNA replicons, whereas NB631 has been identified as a dsRNA element.

NB631 dsRNA is transferred by hyphal anastomosis, like other *C. parasitica* RNA replicons; however, unlike those, and other viruses of filamentous fungi, it is also efficiently transmitted by meiotic spore formation if the female parent had the virus.²⁸³

RETROVIRUSES (RETROELEMENTS)

Retroviruses, Retrotransposons, Retroposons, and Retrointrons

Retroelements (Table 74.2) all share their use of reverse transcriptase in their propagation. The retrotransposons of fungi and parasitic microorganisms (Table 74.3) resemble

TABLE 74.3 Retrotransposons of Simple Eukaryotes

Retrovirus (copy #)	Host species	LTRs	ϵ (unique)	Group ^a	Reference

^aBased on amino acid sequence homology and gene order, retrotransposons may be divided into those similar to the *copia* element or the *gypsy* element of *Drosophila*.⁸² Copy numbers of *S. cerevisiae* retrotransposons in the genome are from reference 154. LINE-like elements are retroposons, lacking LTRs.

LTRs, long terminal repeats; LINEs, long interspersed elements.

FIGURE 74.7. The Ty replication cycle. It is likely that all retrotransposons follow this cycle.

mammalian retroviruses in all essentials except for their lacking an *env* (envelope) gene and, in part for this reason, are restricted to propagation without leaving the intracellular environment (Fig. 74.7). Nonetheless, the frequency with which these cells mate in nature is so high that most of these elements are widely distributed in their respective species. The retrotransposons are one step further removed in that they lack the long terminal repeat (LTR) structure, and their transposition process differs from those of the other groups. These elements resemble the mammalian LINE elements but have the advantage of readily detectable transposition and facile host genetics for their study. For example, Tad, of *Neurospora*, can retrotranspose between nuclei of a heterokaryon.²⁰⁸ Excellent reviews of retrotransposons are available.^{32,153,227,313,368}

A group of reverse transcriptase encoding introns in mitochondrial DNA of *S. cerevisiae* has also been identified (199; reviewed in 220,221). These are introns aI1 and aI2 of the cytochrome oxidase subunit I (COX1) gene. These introns are capable of retrotransposition both into their normal location and into heterologous locations, both *in vitro*¹⁹⁹ and *in vivo*.²⁶⁰ These retroelements lack LTRs and have only a single ORF. Their properties suggest that introns may have begun as parasitic elements.

The retrotransposons are also divided based on amino acid sequence homologies and gene order in the *pol* domain

into the *copia*-like and the *gypsy*-like elements. *Copia* and *gypsy* are retroelements of *Drosophila*. Because Ty3 is more similar to *gypsy* than to Ty1, it is likely that Ty3 and Ty1 entered the yeast genomes at different times and that horizontal transfer of these elements occurs.

Structure of Tys and Other Retroelements

The Ty elements of *S. cerevisiae* each have LTRs of 245 to 371 bp, separated by a unique region of 4.7 to 5.6 kb³⁰ (Fig. 74.8). The major Ty RNA transcript begins within the 5' LTR (at base 241 from the 5' end in Ty1) and ends at base 289 of the 3' LTR, 45 bp from the 3' end of the element (see Fig. 74.8). This provides the basis for the conventional division of retroviral LTRs into the U3 region (present only at the 3' end of the Ty RNA but located at the 5' end of the LTR), the R region (repeated at both ends of Ty RNA), and the U5 region (present only near the 5' end of Ty RNA but at the 3' end of the LTR).

Ty1 through Ty4 all have two overlapping ORFs: TYA, corresponding to *gag*, and TYB, homologous to the *pol* of mammalian retroviruses. Like mammalian retroviruses and *gypsy*, Ty3 has the gene order protease (PR)–reverse transcriptase (RT)–RNase H (RH)–integrase (IN) in the *pol* ORF,¹⁷¹ whereas Ty1 and Ty2 have the *copia* order PR-IN-RT-RH.^{72,374}

FIGURE 74.8. Genome structure and expression of Ty1. Gag and Gag-Pol are the primary translation products, which are processed by cleavage with the viral protease to form the proteins shown. (Adapted from Garfinkel DJ, Hedge A-M, Youngren SD, et al. Proteolytic processing of *pol-TYB* proteins from the yeast retrotransposon Ty1. *J Virol* 1991;65:4573–4581.)

Replication Cycle of *Saccharomyces cerevisiae* Ty Elements

The Ty replication cycle resembles that of mammalian retroviruses but begins and ends with the integrated form of the genome (see Fig. 74.7). Ty transcripts made with RNA polymerase II are translated to make the Gag and Gag-Pol fusion proteins. These proteins assemble, packaging the Ty RNA to make particles that are homologs of the core particles of retroviruses. The reverse transcriptase and RNase H make a dsDNA copy of the genome, and integrase inserts this into the genome, producing a short repeat of the chromosomal integration site.

Reverse Transcription

The reverse transcriptase and RNase H—homologous domains are present in the Ty1 particles as a 60-kD protein that is produced by proteolytic processing of the 190-kD Gag-Pol fusion protein¹⁵⁴ (see Fig. 74.8). Isolated Ty1 particles have reverse transcriptase that is active on either the endogenous Ty1 RNA or externally added templates. The Ty particles are also open to externally added enzymes, indicating that they are not impermeable shells but have pores. This porous structure may help explain how pseudogene formation can

occur.⁹⁷ Extraction of active polymerase requires that the C-terminal part of integrase be covalently attached, reflecting the likely cooperation of reverse transcriptase and integrase in virions.³⁸⁹

The mechanism of reverse transcription of Ty RNA is largely the same as that for mammalian retroviruses. The primer for reverse transcription is tRNA_{Met} , with ten nucleotides of the 3' acceptor stem complementary to a site on the Ty1 positive strand just 3' to the 5' LTR, called the negative primer binding site (–PBS).⁵⁴ This tRNA is specifically packaged in viral particles.⁵⁴ Interestingly, although the primer function of the initiator tRNA_{Met} depends on its complementarity with the –PBS, its packaging is independent of this complementarity.⁵⁴ This indicates that the tRNA_{Met} is recognized by some other component of the Ty virus particle and that it is probably not the acceptor stem of the tRNA that is recognized. Ty1 cDNA synthesis unexpectedly requires *DBR1*, encoding the enzyme that debranches the lariat structure produced by intron excision by cleaving the 2'-5' linkage at the branchpoint.⁵³ Dbr1p acts by cleaving a 2'->5' linkage between the ribonucleotide at the 5' end of Ty1 RNA and an internal Ty1 ribonucleotide.⁵⁹

Integration

Ty3 shows a tight specificity for target sites, integrating 16 or 17 bp upstream of the 5' ends of tRNA coding regions.⁵¹ The DRE element of *Dictyostelium discoideum* and the spliced leader-specific elements SLACS, CZAR, and CRE1 of trypanosomes have a similar integration target specificity.^{3,149,240} Other genes transcribed by RNA polymerase III, such as 5S rRNA and U6 small nuclear RNA, similarly are targets for Ty3.⁵¹ The basis for this site specificity is a specific interaction of Ty3 integrase with the PolIII transcription factor TFIIC¹⁰ and recognition of the TPB and Brf1 subunits of TFIIB.⁴⁰¹ Thus, the integration apparatus recognizes the transcription apparatus, not the transcription initiation site or the promoter itself.

Other Tys are capable of insertion at many different sites, with Ty1 producing a five-bp duplication of the target DNA¹³³; however, these sites tend to be within 750 bases of a tRNA gene or other RNA polymerase III-transcribed gene.²⁰³ Ty1 insertions in RNA *pol* II-transcribed genes tend to be in the 5' part of the *URA3*, *LYS2*, and *CAN1* genes,^{117,230,265} with control regions targeted far more often than the ORFs.

An *in vitro* integration system using Ty1 viral particles produced from an element carrying a copy of the *Escherichia coli supF* gene and, as target, λ DNA from a multiple amber mutant suppressible by *supF* shows that linear dsDNA substrates carrying the terminal 12 bp at each end of the LTR are sufficient for the integration reaction to occur at normal efficiency.¹¹⁸ There are also no nucleotide requirements. The substrate DNA must have 3' hydroxyls, suggesting that the reaction involves covalent attachment of these 3' ends to the target DNA. Unlike mammalian retroviruses, Ty1's IN does not remove two terminal bases in the process of integration,¹¹⁸ probably because in Ty1 the -PBS is immediately adjacent to the U5 part of the LTR. In fact, the purified IN protein is capable of carrying out an integration model reaction without other components of the viral particle.²⁵⁸

Expression

CONTROL OF TRANSCRIPTION

Transcription of Ty1, Ty2, Ty4, and Ty5 is inhibited in diploid cells by the action of the $\alpha 1/\alpha 2$ encoded by the *MAT* locus.⁷⁴ In the wild, the haploid phase for yeast is transient, and cells soon mate and spend most of their time as diploids. Is the 20 times higher transcription of Ty1 in haploids a preparation for mating and the possible opportunity to hop into a new genome?

Transcription of Ty3 and Ty5 are derepressed by exposure of cells to the mating pheromones.^{73,198,364} Ty3 transposition is, in fact, induced in mating cells, and Ty3 transposing from the genome of one mating partner to that of the other occurs at high rates.²⁰⁹ Here, the interpretation of preparation to transpos into the potentially Ty3-free genome of the mating partner seems clear.

Filamentous growth, associated with starvation, also mobilizes Ty as a result of elevated transcription produced by the Kss1 MAP kinase cascade.⁷⁵ Again, a stressful condition results in Ty mobility.

DNA damage, induced by ultraviolet irradiation or 4-nitroquinoline-1-oxide also induce Ty1 transposition by inducing transcription of the element.³⁷ Is this effect adaptive for Ty1 as a first step in finding a new home, or is it a consequence of a failure of the host anti-Ty system?

Retroelements all must cajole the cellular RNA polymerase II into transcribing their proviral form to make viral RNA. They are constrained, however, to place the controlling sequences inside the limits of the element. Whereas most mammalian retroviruses have enhancers in their LTRs upstream of the start site of transcription, Ty1 and Ty2 elements have major transcriptional control sequences downstream of both the transcript start site and the translation start site, most of them inside the unique region. Ty1 has two major downstream sites responsible for its haploid-specific transcription: the sterile-responsive element (SRE) binds Ste12p, and another site (block II or PRTF) binds Mcm1p.^{74,121}

EFFECT OF TY INSERTION ON CELLULAR GENES

Insertion of Ty elements into the control regions of cellular genes can activate, inactivate, or alter the control of the target gene (122,392; reviewed in 227). The Ty insertions often move the normal regulatory sequences 5 kb away from the target gene, eliminating the normal regulation. Insertions of Ty whose 5' end is close to the 5' end of the target gene impose the Ty transcriptional control on the target gene. This produces a divergent transcription of the Ty element and the target gene; however, both are under mating type control because of the effect of the Ty control region.

CHROMOSOMAL GENES REGULATING TY TRANSCRIPTION

Mutant cellular genes that have come under control of Ty1 have been used extensively to investigate the cellular genes affecting the transcription of Ty1 itself.^{71,394,395} Second-site mutations (suppressors) that restore the normal expression of the target genes have defined a large group of genes, called *SPT*, that include the TATA binding factor TFIID, the genes encoding histones, and many general transcription factors with effects on many genes (e.g., *SNF2*, *SNF5*, *SNF6*, *GAL11*, *SIN1*). In addition, the control of the target genes by mating type and mating pheromones have led to studies of effects of the mating type and pheromone control pathway genes on Ty itself. For example, *STE12* controls Ty1 transcription, as do the genes upstream of *STE12* in the mating type control kinase cascade.¹²³

+1 RIBOSOMAL FRAMESHIFTING

Like mammalian retroviruses, Ty elements direct the synthesis of a Gag protein and a Gag-Pol fusion protein (see Fig. 74.9). For reasons that are not yet clear, each of the *Saccharomyces* Ty elements uses +1 ribosomal frameshifting, whereas animal retroviruses all use -1 frameshifting (or read-through of a terminator) to make Gag-Pol (reviewed in 15,339). As shown by studies of the L-A dsRNA virus, yeast can perform -1 ribosomal frameshifts by the same simultaneous slippage mechanism used by retroviruses.

The mechanisms of the +1 frameshifts in Ty1 or Ty2 (see Fig. 74.9) and Ty3 all involve the combination of starvation for a rare tRNA and an unusual tRNA able to perform the frameshift.^{22,134} In the case of Ty1, the slippery site on the mRNA is CUU-AGG-C. The ribosomes are slowed by the AGG codon at the ribosomal A site. This codon is recognized by a tRNA^{Arg} that is present in low abundance in yeast, thus it is referred to as a hungry codon. The tRNA^{Leu}, located at the P site while the A site is waiting for the AGG codon to be occupied, has as its anticodon UAG, and it is capable of pairing with either the 0 frame CUU codon or the +1 frame codon UUA.

FIGURE 74.9. Mechanism postulated for +1 ribosomal frameshifting of Ty1. Ty3

frameshifting involves the new tRNA pairing in the +1 frame without a shift of the peptidyl transfer RNA as for Ty1.³⁶⁷ (Adapted from Belcourt MF, Farabaugh PJ. Ribosomal frameshifting in the yeast retrotransposon Ty tRNAs induce slippage on a 7 nucleotide minimal site. *Cell* 1990;62:339–352).

When it slips into the +1 frame, the GGC codon can be easily recognized by an abundant tRNA^{Gly} species, and the ribosomes then continue in the +1 pol reading frame to make Gag-Pol fusion protein.²²

The efficiency of the Ty1 +1 ribosomal frameshift depends on the scarcity of the tRNA^{Arg} recognizing the AGG codon. Thus, artificially oversupplying this tRNA lowers frameshift efficiency²² and also lowers transposition frequency.³⁹⁷ Likewise, deletion of the gene for this tRNA^{Arg} increases the efficiency of frameshifting and lowers the frequency of transposition.¹⁹⁷ Like the similar experiments done with the L-A dsRNA virus of *S. cerevisiae*, these results suggest that drugs affecting frameshifting efficiency might be useful as antivirals.

The Ty3 frameshift site is GCG-AGU-U, and, like that of Ty1, it is based on a hungry codon in the ribosomal A site, namely AGU.¹³⁴ AGU is recognized by a low-abundance tRNA^{Ser}, thus the ribosome pauses at this point. However, the tRNA^{Ala}_{CCG} that decodes the GCG codon in the P site cannot slip +1 and re-pair. Rather, it is believed that the valine tRNA simply pairs out of frame.³⁶⁷ A downstream sequence may stimulate Ty3 frameshifting by interacting with rRNA.³³⁹

PROTEOLYTIC PROCESSING AND PHOSPHORYLATION

Ty1 Gag is expressed as a primary translation product of about 58 kd, most of which is processed by the Ty1 protease to form the 54-kd major particle protein.¹ After Pol is synthesized as a 190-kd Gag-Pol fusion protein, it is processed through several intermediates to form a 23-kd protease, the 90-kd integrase, and the 60-kd reverse transcriptase–RNase H¹⁵⁴ (see Fig. 74.8).

PACKAGING AND ASSEMBLY

The Ty1 RNA site determining packaging has been localized to within a 381-nucleotide region between nucleotides 239 and 620.³⁹⁹ The RNA structure recognized and the parts of Gag or Gag-Pol proteins that recognize this region have not yet been determined.

Ty5 and Ty1 mRNA and Gag localize in cytoplasmic particles (T-bodies) thought to be involved in viral particle assembly.^{21,55,238} Assembly of T-bodies requires components of the mRNA-processing bodies referred to as P-bodies (Dhh1p, Lsm1p, Pat1p); however, T-bodies are distinct from P-bodies in the case of Ty1^{55,111} but may be identical in the case of Ty3.²¹ Mutants in these P-body components are defective for retrotransposition, as well as for cDNA accumulation. Retrotransposition requires not only the P-body structure but also its RNA-degrading enzymatic activities, such as the decapping enzyme *Dcp1/2* and 5' to 3' exoribonuclease *Xrn1p/Ski1p*.^{55,111} Because these activities also degrade Ty1 antisense

RNA, it is possible that their effects on Ty1 are a mix of effects on packaging and effects on the antisense copy number control system.

Host Limitations on Ty Transposition Efficiency

Although normal cells have about 35 chromosomal copies of Ty1, most of which are probably transposition competent,⁸⁶ transposition is a relatively rare event, and the host has several levels of defense against Ty1 attack.²⁴⁹ In normal cells, approximately 1% of mRNA is Ty1 mRNA; however, Ty1 protein levels are low, in part a result of sequestration of Ty1 mRNA in P-body-related particles in an untranslated state.¹¹¹

Many studies of the mechanism of transposition have used a high-copy plasmid with a GAL1-promoted Ty1 carrying a marker (such as *HIS3* in the antisense orientation with an artificial intron in the sense orientation) to facilitate detection of transposition.⁸⁴ When Ty1 transposition is induced with such a plasmid, although Ty1 RNA is increased only a few fold over that derived from the normal chromosomal Ty1 copies, the frequency of transposition increases about 100-fold, suggesting a block to transposition that is saturable by Ty1 mRNA.⁸³ This blockade of Ty1 transposition is enhanced by an increase of Ty1 copy number.¹⁵⁵ Transposition is normally blocked at several levels, including transcription,¹⁸⁸ translation and processing of viral proteins,^{75,83} virus assembly, cDNA synthesis or stability, and chromatin structure (see later discussion). Many host genes have been identified whose mutation derepresses Ty1 transposition (reviewed in 227), analogous to the effect of ski mutations on RNA virus copy number (see earlier discussion). Recently, antisense RNA transcribed from Ty1 itself has been found to play an important role in copy number control.^{26,245} Antisense RNAs transcribed from the 5' end of the Gag ORF and incorporated into viral particles are necessary for this copy number control.^{26,245} The antisense RNAs decrease the level of Gag, integrase, and reverse transcriptase, and block cDNA synthesis, apparently acting at a posttranslational level.²⁴⁵ Mutation of components of the 5' to 3' RNA decay pathway, particularly the 5' to 3' exoribonucleases *xrn1* and *kem1*, result in elevated antisense RNA and decreased Ty1 retrotransposition.^{55,111}

Mutation of the cellular *rad6* gene, encoding a ubiquitin-conjugating enzyme, increases the frequency of Ty transposition at either *URA3* or *CAN1* and changes the distribution of insertions.²⁸⁰ This effect is not caused by altered Ty transcript levels and was seen even when retrotransposition from a GAL1-promoted Ty1 was studied. Rad6p alters chromatin structure by monoubiquitination of histone H2B on Lys123,³⁰⁰ suggesting that the Rad6p effect on Ty1 transposition is on the nature

of the target. Indeed, *rad6* mutations specifically affecting silencing have the same altered Ty1 transposition as the deletion.¹³⁷ Mutation of *CAC3*, encoding a subunit of chromatin assembly factor, and *HIR3*, a histone transcription regulation gene,²⁸⁶ also affects both the frequency of integration and the distribution of insertions by alterations of the structure of the target.¹⁸⁰

Mutation of the *FUS3* MAP kinase results in a more than 20-fold increased Ty1 transposition frequency.⁷⁵ Ty1 transcript levels and primary translation products were not affected by *fus3*; however, virus particle-associated processing products of Pol and Ty cDNA were each elevated 10-fold or more in the mutant. The Fus3 kinase is activated by exposure to the mating pheromones via a cascade of kinases; thus, this explains the inhibition of Ty1 transposition by exposure to mating pheromones.³⁹⁸ Although Fus3 may act indirectly to block Ty1 transposition, several observations suggest a direct action.⁷⁵ Gag is phosphorylated,²⁵² and this phosphorylation is increased concomitant with the inhibition of transposition that occurs when cells are treated with mating pheromone, which is known to activate Fus3.³⁹⁸ Gag has several consensus sites for Fus3 phosphorylation.

Mutations in more than 20 genes encoding DNA replication and repair components show derepression of Ty1 retrotransposition (reviewed in 249). For example, mutants in *SSL2* and *RAD3*, encoding excision-repair DNA helicases, show elevated retrotransposition,²²³ as do mutants in *RRM3*, encoding a helicase that promotes replication through DNA-protein complexes.⁸⁵ There is no elevation of Ty1 transcripts; however, the level of Ty1 cDNA is elevated.^{85,223,343} This group of mutations is known to activate the DNA damage checkpoint pathway or the DNA replication stress pathway, and their derepression of Ty1 transposition is prevented by mutation of elements of the checkpoint pathways, such as *rad53*, *rad9*, *rad24*, *mec1*, and *dun1*.⁸⁵ Thus, DNA damage or replication arrest from a host of sources, by activating the checkpoint pathways, turns on Ty1 retrotransposition. Although the mechanism of this effect is not yet clear, the best explanation appears to be that cellular conditions at the arrest point in the cell cycle are particularly favorable for transposition.²⁴⁹ There is no evidence that this derepression favors either the yeast host or Ty1.

Ty5 integration is concentrated in regions of heterochromatin, unlikely to be detrimental to the host.⁴⁰⁶ A nine-residue section of the Ty5 integrase determines association with Sir4p, a heterochromatin protein, and hence the site specificity.³⁹⁶ However, this interaction and the corresponding targeting to heterochromatin only occur properly when this targeting domain site is phosphorylated at S1095 by a host kinase.⁸⁷ Under stress conditions, this control system breaks down, the targeting domain is not fully phosphorylated, and integration is random, producing more serious mutations.⁸⁷

The variety of host defenses against Ty1 and Ty5 reflects the dangers inherent in its mobility. Although occasional favorable mutations can result, Ty1 copy number is inversely correlated with fitness.³⁹⁰

Schizosaccharomyces pombe Retroelements

The Tf1 and Tf2 elements of *Schizosaccharomyces pombe* are unusual in that a single ORF encodes both Gag and Pol.²²⁸ From the primary 140-kD translation product, the viral pro-

tease cleaves the proteins that form the viral particles.²²⁹ In view of the strict requirement for the ratio of Gag to Gag-Pol in Ty1^{197,397} and retroviruses, the assembly process in Tf1 and Tf2 must be significantly different. In log phase cells, the ratio of Gag to IN in particles is close to 1, whereas in stationary cells, it is quite high.⁹ Selective degradation of the non-Gag protein components alters the ratio after particle formation.⁹

The priming mechanism of Tf1 is also unique. Instead of tRNA priming as for other retrotransposons and retroviruses, Tf1 negative-strand DNA synthesis is primed by the first 11 nucleotides at the 5' end of the viral RNA, which is complementary to the primer binding site.²³¹ A hairpin is formed, which is nicked to separate the first 11 nucleotides from the 5' end of the RNA and give it a 3'OH that can serve as a primer for strong-stop DNA synthesis.

Although the *piwi* RNAi system controls retrotransposons in mammals and many other organisms, two chromatin-modifying protein-based systems have been identified in *S. pombe* that silence *Tf2* elements and *Tf2*-derived LTRs and prevent their recombination that could damage the genome.^{48,164} The HIRA complex, a nucleosome-assembly apparatus that includes Hip1, Slm9, and Hip3, is important for the assembly of silencing heterochromatin at various sites, including the *Tf2* retrotransposon.¹⁶⁴ Three homologs of human CENP-B—Abp1, Cbh1, and Cbh2—are involved in a different chromatin silencing system that works by binding to *Tf1* and *Tf2* loci (and lone LTRs) and recruiting the histone deacetylases Clr6 and Clr3 to those sites.⁴⁸ In addition to the silencing produced by localized histone deacetylation, the CENP-B homologs draw together the *Tf* loci into intranuclear bodies, which may facilitate their silencing.⁴⁸

Candida albicans Plasmid Retrotransposon and LINE Elements

Most retrotransposons have minute amounts of cDNA present in normal strains; however, that of *Candida albicans* (pCal) produces 50 to 100 copies per cell of linear dsDNA in a particular strain of *Candida*.²⁴⁸ pCal is a member of the Ty1/*cop* group found in integrated form in most strains, and the basis for its high free levels is not yet known. pCal is also unique among retrotransposons in that it uses read-through of a stop codon to make its Gag-Pol fusion, as in murine leukemia virus.²⁴⁸

C. albicans also carries several families of non-LTR retrotransposons (LINEs), homologous to the mammalian L1 LINE elements.¹⁶² One of these elements, Zorro3, has been shown capable of transposition in *S. cerevisiae*.¹⁰⁹ Non-LTR retroelements have also been identified in *Cryptococcus neoformans*.¹⁶³

Summary of Retroelements

The mating type and pheromone control of Ty transcription is clearly adapted to maximize transposition activity at the time when a potentially unoccupied genome becomes available (mating), and to minimize potential damage to the host, whose health is indispensable for survival. Ty gets moving when the host's genome seems in danger, perhaps in an effort to find a safe haven. The host limits retrotransposition at several levels, apparently to prevent damage to its genome.

The many interesting questions about Ty elements include the following: Why do all Ty's use +1 frameshifting but

mammalian retroviruses use -1 frameshifting or termination read-through to make their Gag-Pol fusion proteins? How does RNA polymerase II know to stop in the 3' LTR but to keep going in the identical sequence in the 5' LTR? The bewildering array of retroelements continues to amaze.

DNA VIRUSES: *CHLORELLA* VIRUSES

Chlorella is a unicellular eukaryotic alga with a rigid cell wall and a single chloroplast (reviewed in 365,393,400). Most *Chlorella* species are free living; however, several, collectively referred to as zoochlorellae, live as endosymbionts (intracellular symbionts) of *Hydra* or *Paramecium*.

An attempt to isolate zoochlorellae free of their *Hydra* or *Paramecium* host often induces multiplication of a virus that grows and kills the zoochlorellae. These viruses are called *Hydra viridis Chlorella* virus (HVCV) or *Paramecium bursaria Chlorella* virus (PBCV). Hundreds of *Chlorella* viruses have been isolated directly from freshwater and are found throughout the world. They are grown on cultured zoochlorellae and form lytic plaques on agar plates.

Chlorella viruses are large (150–230 nm), polyhedral particles containing 5% to 10% lipid. The outer shell is a T = 169 icosahedron, surrounding an inner lipid layer. The dsDNA genome of PBCV-1, the best studied *Chlorella* virus, is 333 kb, one of the largest viruses known. PBCV-1 DNA is linear with (a) terminal inverted repeats of 2.2 kb, (b) terminal hairpin structures, and (c) shorter direct repeats within the inverted terminal repeats. All three characteristics are in common with the poxviruses, vaccinia virus, and African swine fever virus. Some other features are shared with the iridoviruses.

Chlorella virus DNA is heavily methylated, with 5-methylcytosine accounting for as much as 47% of C residues and 6-methyladenine for up to 37% of A residues. Surprisingly, the *Chlorella* viruses encode their own methylases. They also have been found to encode various restriction endonucleases, similar in properties and, in many cases, in specificity to bacterial type II restriction endonucleases. The variety of such methylases and restriction endonucleases has only begun to be explored; however, it is clear that a wide variety of specificities will be found.²⁶⁷ The function of these enzymes is completely unclear, and there is evidence against their being required for either degradation of host DNA or exclusion of other co-infecting viruses (reviewed in 267).

The 54-kd major capsid protein of PBCV-1 has a carbohydrate component of about 5 kd. Unexpectedly, the virus encodes glycosyl transferases and other products that determine the glycosylation of Vp54.³⁷³

The complete sequence of PBCV-1 showed that the 330,742-bp genome encodes enzymes for synthesis of hyaluronic acid, aspartate transcarbamylase (uracil biosynthesis), an EF-3 homolog (translation elongation factor), 10 tRNA genes, one with a small intron, genes with self-splicing type I introns, other genes with spliceosome-dependent introns, protein kinases, a potassium channel protein, and numerous enzymes involved in nucleic acid metabolism.

Large DNA viruses of marine brown algae have also been described (reviewed in 366). The giant *Mimivirus*, with the largest known viral genome, and infecting *Acanthamoeba*, is reviewed in Chapter 71.

PRIONS OF *SACCHAROMYCES* AND *PODOSPORA*

The concept of an infectious protein arose in studies of the transmissible spongiform encephalopathies (TSEs), such as scrapie of sheep, mad cow disease, and Creutzfeldt-Jakob disease of humans (see Chapter 76). Based on genetic evidence (Fig. 74.10), two non-Mendelian genetic elements of *S. cerevisiae*—[URE3] and [PSI]—were identified as prion (infectious protein) forms of Ure2p and Sup35p, respectively.³⁸⁰ This conclusion is supported by extensive further evidence, and both are transmissible amyloidoses, a remarkably close parallel to the mammalian disease. Two further amyloid-based prions—[Het-s] of the filamentous fungus *Podospora anserina*⁷⁹ and [PIN⁺] of *S. cerevisiae*⁹⁴—were next found and have been studied extensively. An infectious protein consisting of an enzyme whose active form is essential for activation of its own inactive precursor can also be an infectious protein, and two such cases have been described.^{202,299} Recently, several other yeast prions have been reported (Table 74.4).

[URE3]—A Transmissible Amyloidosis of Ure2p

When yeast has a good nitrogen source, such as ammonia, Ure2p, by binding the transcription factor Gln3p, shuts off transcription of genes encoding enzymes and transporters needed for the utilization of poor nitrogen sources, such as *DAL5*, encoding the allantoin transporter.⁷⁷ In 1971, Lacroute described a non-Mendelian genetic element of *S. cerevisiae* called [URE3], which allowed cells to take up ureidosuccinate despite the presence of a rich nitrogen source.²¹⁹ Ureidosuccinate is the product of aspartate transcarbamylase (*URA2*) in uracil biosynthesis. Because of chance resemblance to allantoin (a poor nitrogen source), it is taken up from the medium by Dal5p, and *DAL5* is repressed by ammonium via Ure2p action. Thus, [URE3] *ura2* strains can grow on ureidosuccinate in the presence of ammonia, whereas [ure-o] cells (lacking [URE3]) cannot. Fusing the *DAL5* promoter to the *ADE1* ORF allows assaying [URE3] by adenine prototrophy.³¹⁸

Genetic Evidence that [URE3] Is a Prion

Three lines of genetic evidence first showed that [URE3] is actually an altered form of Ure2p that has lost its activity in repressing nitrogen metabolic enzymes through Gln3p but has acquired the ability to convert the normal Ure2p to this altered form³⁸⁰ (see Fig. 74.10). First, [URE3] is efficiently cured by growth of cells on guanidine HCl; however, the curing is reversible in that [URE3] derivatives may again be selected from the cured strain.³⁸⁰ Second, overproduction of Ure2p leads to a 20- to 100-fold increase in the frequency with which [URE3] arises *de novo*.³⁸⁰ Third, Ure2p is required for propagation of the [URE3] nonchromosomal gene, but the phenotypes of *ure2Δ* and [URE3] are essentially identical.^{2,380} These three features are strongly predicted by the prion model, although not if [URE3] were a nucleic acid replicon—a virus or plasmid.³⁸⁰ These three properties, none of which were known for the mammalian TSEs, also served to identify [PSI⁺] as a prion form of Sup35p,³⁸⁰ [PIN⁺] as a prion of Rnq1p,⁹⁴ and other prions.

genetic properties of a yeast prion

FIGURE 74.10. Three genetic criteria for a prion. These are unusual features, expected of a prion but not of a nucleic acid replicon. (Adapted from Wickner RB. [URE3] as an altered URE2 protein: evidence for a prion analog in *S. cerevisiae*. *Science* 1994;264:566–569.)

Ure2p is partially protease resistant in extracts of [URE3] strains, like the amyloid of PrP in brains of TSE-infected animals.²⁴⁴ Moreover, the generation and propagation of [URE3] was unaffected by the repression or derepression of nitrogen regulation, eliminating some alternative models. [URE3] truly does arise *de novo*, and it is the Ure2 protein, not the *URE2* mRNA or the copy number of the *URE2* gene, that induces [URE3] to arise.²⁴³

Domains of Ure2p

Ure2p is composed of a C-terminal functional domain, whose structure resembles glutathione-S-transferases (residues 95–354),^{34,244,363} and an unstructured N-terminal domain (residues 1–94).^{244,281} Ure2p^{90–354} is sufficient, if overexpressed, for nitrogen regulation but is rapidly degraded without the N-terminal residues.³²⁹ This stabilization domain is also the part of the molecule responsible for the prion change (the prion domain) and comprises roughly the N-terminal 65 residues

(244; Fig. 74.11). [URE3] is efficiently transmitted by cytoplasmic mixing to cells expressing only Ure2p^{1–65} from those expressing the full-length protein. The cells expressing only Ure2p^{1–65} stably propagate the prion and efficiently transmit it again to cells expressing the full-length Ure2p.²⁴³ On conversion to the infectious amyloid form, the C-terminal domain is largely unchanged in structure,^{11,17} and the prion domain (residues 1–65) assumes an extremely stable amyloid form.^{18,351} Residues 66 through 94 remain unstructured in the amyloid form and are called the *tether* because they attach the structured C-termini to the structured amyloid core.

Infectious Amyloid of Ure2p Is [URE3]

Ure2p–green fluorescent protein fusions are aggregated in [URE3] cells, indicating that aggregation is involved in the [URE3] change.¹¹⁴ The Ure2p prion domain synthetic peptide can form amyloid, and this domain also directs the conversion

whose infectivity is nearly as high as that of extracts. Infectivity resides entirely in the N-terminal prion domain, again showing its central role.³⁵

[PSI]—A Transmissible Amyloidosis of Sup35p

In 1965, Cox⁸⁰ described [PSI], a non-Mendelian genetic element of *S. cerevisiae* that increases the efficiency of nonsense suppression by classical tRNA suppressors. Like [URE3] and Ure2p, [PSI] is reversibly curable,^{234,333} overexpression of Sup35p increases the frequency with which [PSI] arises by 100-fold,^{60,96} the phenotype of [PSI] is like that of *sup35* mutants, and *SUP35* is necessary for propagation of [PSI].^{108,352} This logical parallel with [URE3] and Ure2p indicates that [PSI] is also a prion form of Sup35p.³⁸⁰

Infectious Amyloid of Sup35p

Sup35p is aggregated in [PSI+] strains but not in [psi-] strains,^{276,279} and the *in vitro* aggregation of native soluble Sup35p seeded by the prion form from [PSI+] cells will continue indefinitely as long as fresh native Sup35p is supplied.²⁷⁸ Further, synthetic prion domain peptide spontaneously forms amyloid *in vitro*.²⁰⁷ In addition, the full-length Sup35p, made in *E. coli*, forms β -sheet-rich filaments spontaneously when diluted out of denaturant, a process that can be accelerated specifically by an extract from [PSI+] cells.¹⁶⁰

Amyloid formed from recombinant Sup35p transmits [PSI+] to cells, inducing the appearance of several prion variants.^{206,346} Extracts of cells bearing a variant are infectious and transmit the variant carried by the strain from which the extract was made. Moreover, seeding soluble Sup35p with an extract amplifies amyloid transmitting that prion variant. Adjusting the conditions under which amyloid forms spontaneously strongly biases the variant encoded by the amyloid formed.³⁴⁶ These results are useful in studies of the structural differences between prion variants.

[PIN+]—A Prion that Generates Other Prions

Derkatch et al⁹⁵ found that whereas overproduction of Sup35p induces the high frequency appearance of [PSI+] in some strains, others did not show this effect. Their analysis showed that this effect was attributable to the presence of a nonchromosomal genetic element in the strains in which [PSI+] generation was inducible. The Rnq1 (rich in N and Q) protein showed a self-propagating aggregation,³³⁶ and indeed Rnq1 amyloid formation proved to be the basis of the [PIN+] nonchromosomal gene.⁹⁴ Overproduction of other N/Q rich proteins likewise has [PIN+]-like activity (without being themselves prions), as does the [URE3] prion.⁹⁴ Moreover, [PIN+] also modestly promotes *de novo* generation of [URE3].³⁶ [PIN+] probably promotes generation of prions by other N/Q rich proteins by rare cross-seeding.

Recombinant Rnq1p also forms amyloid *in vitro*,³³⁶ and this amyloid can infect yeast cells with the [PIN+] prion.²⁷⁵

[Het-s]—A Prion of *Podospira* Responsible for a Normal Function

When two colonies of the same strain of filamentous fungus meet, they fuse their cellular processes (called *hyphae*) in a process referred to as hyphal anastomosis or vegetative fusion or heterokaryon formation. This allows exchange of cytoplasm

Heterokaryon Incompatibility in *Podospira* requires the [Het-s] prion

FIGURE 74.12. The [Het-s] prion of *Podospira anserina* is required for heterokaryon incompatibility. (Adapted from Coustou V, Deleu C, Saupe S, et al. The protein product of the *het-s* heterokaryon incompatibility gene of the fungus *Podospira anserina* behaves as a prion analog. *Proc Natl Acad Sci U S A* 1997;94:9773–9778.)

and even nuclei and allows cooperation between the colonies in obtaining nutrients. However, a virus initially present in only one colony will spread throughout the other colony; thus, the process is tightly controlled, requiring identity of the two strains at 6 to 10 special chromosomal loci, called *het* loci in *Podospira anserina*. Fusion of two strains that differ at a *het* locus begins; however, it is quickly arrested with death of the few fused hyphae and formation of a barrier to further hyphal fusion. This is referred to as the heterokaryon incompatibility reaction (Fig. 74.12) (reviewed in 316).

One of the *het* genes of *Podospira anserina* is *het-s*, with alleles *het-s* and *het-S* encoding a 289-residue protein differing at 14 positions,³⁶¹ although the difference at residue 33 is sufficient to trigger the incompatibility reaction.⁹³

Rizet²⁹⁸ found that *het-s* strains could show the incompatibility reaction only if they also carried a non-Mendelian genetic element referred to as [Het-s]. [Het-s] could be “cured” from a male strain by mating; however, from the cured strain, [Het-s] cells arose at a frequency of about 10^{-7} .²⁰ This is the *reversible curing* criteria for a prion.

Coustou et al⁷⁹ have made the case that [Het-s] is a prion of the protein encoded by *het-s*. They showed that overproduction of the Het-s protein increased the frequency with which [Het-s] arose, and that the Het-s protein is relatively protease resistant in strains carrying [Het-s]. Moreover, deletion of the *het-s* gene makes a cell unable to propagate the [Het-s] non-Mendelian genetic element.⁷⁹

The prion domain of HET-s is the C-terminal residues 218 through 289, of which residues 228 through 289 are unstructured in the native form.¹³ The HET-s prion domain is not N/Q rich but forms amyloid filaments *in vitro* that are infectious for cells not carrying the prion.²³⁶ The demonstration that amyloid formed *in vitro* from recombinant HET-s protein was the first demonstration of its kind for any prion.²³⁶

Beyond its obvious interest as a new prion, [Het-s] is particularly important because it is the first case in which a prion appears to be responsible for a normal cellular function. Heterokaryon incompatibility is observed in most filamentous fungi, usually controlled by chromosomal genes that have no particularly unusual features. In this case, it requires the [Het-s] prion to be observed. This suggests that other prions may be found responsible for normal cellular functions.

However, another interpretation of [Het-s] is possible, based on a [Het-s]-based meiotic drive system. Mating a female *het-s* [Het-s] strain with a *het-S* strain results in death of *het-S* meiotic segregants that received [Het-s] cytoplasm.⁸⁸ Thus, one could view the [Het-s] prion as a device for the preferential inheritance of the *het-s* allele by a meiotic drive mechanism.

Prion Variants

Strains of the mammalian TSEs were described early on, characterized by different incubation period, symptoms and signs, and distributions of brain lesions.⁴² Independent isolates of [PSI⁺], [URE3], or [PIN⁺] may likewise have various intensity of phenotype or stability.^{36,96,318} These prion variants breed true, and extracts of a strain carrying a given variant of [PSI⁺] or [URE3] transmit almost exclusively that variant by transformation.^{35,206,346} It is clear that different [PSI⁺] prion variants have different amyloid structures,³⁴⁷ and one of the main challenges is to determine these structural differences (Fig. 74.13).

It is striking that only one variant of [Het-s] has been described. Because [Het-s] is either carrying out a function for the host or is a part of a meiotic drive system, it is in either case selected in evolution to be a prion. The protein sequence has presumably been selected to efficiently form the single prion variant that carries out this function.

Structures of Yeast Prion Amyloids Explain Variant Propagation

Ure2p and Sup35p prion domain amyloids have the cross- β -sheet structure typical of amyloids, meaning that the β -strands run perpendicular to the filament long axis.^{16,210,351} Infectious prion domain amyloids of recombinant Sup35p, Ure2p, and

Rnq1p each have a parallel in-register β -sheet structure based on solid-state nuclear magnetic resonance (NMR) studies,^{19,330,382} with identical residues in adjacent molecules aligned in a row along the long axis of the filament (Fig. 74.14). The mass per unit length of Ure2p, Sup35p, and Rnq1p prion domain filaments is in each case the one monomer per 4.7 Å expected for this structure.^{18,57,98} The diameters of the filaments^{207,351,382} show that these filaments must be multiply folded along the filament axis (see Fig. 74.14). This structure is like that found for amyloids of A β , amylin, α -synuclein, β 2-microglobulin, tau, and most other human pathologic amyloids (reviewed in 239,362).

The in-register parallel β -sheet structure is maintained by the positive interactions among identical aligned amino acid side chains—H-bonds between the amide side chains of glutamines or asparagines, H-bonds between the –OH groups of serine or threonine side chains, or hydrophobic interactions among hydrophobic amino acid side chains. These interactions demand that identical residues be aligned. The same interactions direct a monomer joining the end of the amyloid filament to assume the structure of the other molecules in the filament.³⁸⁵ Thus, although any of many different parallel

FIGURE 74.13. A single protein sequence can stably propagate any of several prion variants, each corresponding to a different amyloid structure.

FIGURE 74.14. Structures of prion amyloids. **A:** Infectious amyloid of HET-s²¹⁸⁻²⁸⁹ has a two-turn β helix structure (Adapted from Wasmer C, Lange A, Van Melckebeke H, et al. Amyloid fibrils of the HET-s (218-279) prion form a beta solenoid with a triangular hydrophobic core. *Science* 2008;319:1523–1526). **B:** Infectious amyloid of Ure2p¹⁻⁶⁵, Sup35p¹⁻²⁵³, and Rnq1p¹⁵³⁻⁴⁰⁵ each have an in-register parallel beta sheet architecture.^{19,330,382}

FIGURE 74.15. Prion amyloid structure can be templated by the structure of molecules in the filament. As a new monomer joins the filament interactions of side chains at the end of the filament with those of the new monomer force the new monomer to assume the same structure as the rest of the monomers in the filament. Different filaments may have different locations of the folds (different turn locations) and different extents of the β -sheet structure; however, this information is transmitted to new monomers joining the filament.^{383,385}

in-register structures may form at the time of filament initiation, the location of the folds of the sheet, and the extent of the β -sheet structure will be propagated as the filament is elongated by this mechanism (Fig. 74.15). This mechanism^{383,385} can explain how a protein can template its own conformation (just as DNA can template its own sequence), and thus how proteins can be genes.

HET-s Prion Amyloid Structure

Consistent with its forming only a single prion variant *in vivo*, the HET-s protein prion domain forms a very well defined amyloid structure *in vitro*. This unique structure thus produces very sharp cross peaks in solid-state NMR, making possible the determination of its detailed structure.^{297,375} This structure is a β helix, with two turns of the helix per HET-s molecule (see Fig. 74.14). Interestingly, the HET-s prion domain includes two imperfect direct repeat sequences, and these repeats are aligned in the β helix structure, producing an effect somewhat similar to the parallel in-register architecture of the yeast prions. How this structure is uniquely specified and how interaction of the HET-s amyloid and soluble HET-S produces cell death are important remaining problems.

[URE3] and [PSI] are Diseases of Yeast

Although mammalian prion infections are uniformly fatal, the yeast and fungal prions are often compatible with robust growth. This, in part, led to the suggestion that yeast prions could benefit their host, and it was reported that [PSI+] conferred resistance to high temperature or high ethanol stress.¹¹³ Further studies showed that this observation was not general, and that under most conditions tested, [PSI+] was a disadvantage to the host.³⁵⁹ Nonetheless, because in a minority of conditions [PSI+] appeared to be an advantage, although varying with the yeast strain, it was proposed that [PSI+] helps yeast evolve by allowing the yeast to resist stress until mutation or recombination can produce a stress-resistant genotype.³⁵⁹ Although these results were not consistently repeatable,²⁶⁴ the notion of beneficial yeast prions has gained some currency.³³² Because some Sup35 of some other species can form

prions,^{61,218,314} it was inferred that prion-forming ability is selected by evolution and must therefore benefit the host.³³² Similarly, the conservation of sequences in the prion domains of Sup35p and Ure2p was interpreted to mean that prion-forming ability was selected by evolution.¹⁷²

Several approaches have been taken to evaluate whether yeast prions are diseases or beneficial. Yeast prions are infectious and can be very stable. Moreover, they arise *de novo* in about one in 10^6 cells, thus no substantial population can be isolated from them. If they were advantageous to yeast, they would surely be often found in the wild. A survey of 70 wild yeast strains has failed to turn up any strains carrying either [URE3] or [PSI+], indicating that both are a net disadvantage to the host. In contrast, the 2 μ DNA plasmid, the L-BC dsRNA viruses, and the 20S and 23S ssRNA replicons were found in 38, 8, 14, and 1 strains, respectively, although none of these selfish infectious nucleic acids encode anything but proteins to promote their own duplication.²⁶³

The notion that conservation of prion-forming ability implies a benefit of prions to the host has been discredited by the finding that prion-forming ability of Ure2p and Sup35p is not conserved, even within *Saccharomyces*,^{115,312} and that sequence conservation is not needed for conserving prion-forming ability^{307,308}; therefore, sequences in the prion domains must be conserved for another reason.

Indeed, the prion domains of Sup35p and Ure2p each have normal nonprion functions. The N-terminal domain of Sup35p of yeast and humans interacts with the poly(A) binding protein and poly(A) shortening enzymes to assist in general mRNA turnover.^{78,147,177,178} The Ure2p prion domain protects the protein from rapid degradation and thus is necessary for proper nitrogen regulation.³²⁹ These domains are preserved for their normal functions, not for prion formation.

Finally, the premise that [PSI+] and [URE3] are generally not harmful to their host has been disproven by the finding that lethal or severely detrimental variants of [PSI+] are actually more common than the usually studied mild variants.²⁵⁰ These “killer [PSI]” variants probably inactivate nearly all of the essential Sup35p and are not found in the usual selection procedure. [URE3] variants that severely impair growth in strains whose growth is not slowed by *ure2 Δ* are also common²⁵⁰ and must be owing to a toxic effect of the Ure2p amyloid. It appears clear that the yeast prions [URE3] and [PSI+] are diseases, like their mammalian counterparts.

Chaperone Involvement in Prion Propagation

Chernoff found that either overproduction of Hsp104p or deletion of the *HSP104* gene resulted in the inability of cells to propagate [PSI]^{62,64} (Fig. 74.16). This finding is important because it at once supported the prion model for [PSI], it was the first proof of involvement of a chaperone in a prion phenomenon, and it provides a potential pathway to treatment of prion diseases. Hsp104 is necessary for the propagation of all known yeast prions except [ISP+].^{305,306} Normal levels of Hsp104 promote [PSI] stability by breaking large filaments into smaller ones, providing new seeds for propagation and infection.^{191,217,268,306,360} The mechanism of [PSI] curing by Hsp104 overproduction is unclear³⁰⁶; however, it apparently involves a different activity from that which produces disaggregation.¹⁸² Hsp70s and Hsp40s are also important for prion propagation, at least in part for their roles with Hsp104.^{6,63,189,192,216,327}

FIGURE 74.16. A: Role of chaperones Hsp104, Hsp70, and Hsp40 in propagation of the prions of *Saccharomyces cerevisiae* (Adapted from Masison DC, Kirkland PA, Sharma D. Influence of Hsp70s and their regulators on yeast prion propagation. *Prion* 2009;3:65–73.) Hsp104 is necessary for [PSI⁺] propagation^{62,64} and for other prions (see text) for breaking filaments to form new seeds,^{81,191,268} as are the cytoplasmic Hsp70s.¹⁹² Hsp40s are also critical for yeast prion propagation.^{259,337} Because Hsp104 cooperates with Hsp70 and Hsp40 in disaggregation,¹⁶¹ it is proposed that they cooperate in extracting monomers from filaments, thereby breaking the fibers.¹⁸² Overproduction of Hsp104 cures the [PSI⁺] prion by a different, but unknown, mechanism. Normal levels of Hsp104 are needed for [PSI⁺] propagation, because it has a role in breaking up aggregates to ensure that each daughter cell gets at least one aggregate. **B:** The bound ATP/ADP status of Hsp70 affects prion propagation as indicated (reviewed in 327).

Hsp90 co-chaperones are also important for prion propagation, although largely because of their interactions with Hsp70s.^{189,216,288}

Other cellular components also affect prion propagation. The ubiquitin system is important in curing of [PSI⁺] by overproduction of Hsp104,^{5,65} and the cytoskeletal protein Sla1p assists prion propagation.¹² Btn2 is an endosome-associated protein involved in protein sorting whose overproduction cures [URE3], apparently by collecting Ure2p aggregates at a single cellular site.²¹⁵

PERSPECTIVES

The discovery of prions of yeast and fungi resolved the debate over whether prions could exist at all and widened the scope of this concept, showing that it is not unique to a single mammalian protein. The yeast system is now being used to explore the mechanisms of amyloid and prion generation and propagation, and to devise approaches to the many heretofore intractable amyloid diseases. Likewise, studies of retroelements, RNA viruses, and DNA viruses of unicellular eukaryotes have provided extensive information about each virus group, with

much of it more easily obtained because of the facile genetics of these systems.

Acknowledgments

Bacteriophages—viruses that infect bacteria—collectively constitute a majority of organisms on planet Earth. Virions of the tailed double-stranded DNA (dsDNA) phages, which are the most easily identified in environmental samples, are present at roughly 10^7 /mL in coastal seawater and at comparably high numbers in numerous other environmental situations examined.¹⁷⁶ A rough calculation indicates that there are about 10^{31} individual tailed phage virions on the planet, a literally astronomical number, which means that if all the tailed phages were laid end to end, they would extend for 200 million light years into intergalactic space.⁷⁴ These numbers become even more impressive when we consider that most bacterial genomes contain from one to two dozen phage genomes as prophages.³⁰ Measurements of the persistence of phages in the environment suggest that the entire population of 10^{31} individual virions turns over every 4 to 5 days,¹⁹³ and this leads to the estimate that it takes roughly 10^{24} productive infections per second to maintain the population—speaking only of the tailed phages.⁷⁴

BRIEF HISTORY

Bacteriophages were discovered in 1915 and 1917, based on their ability to cause clearing (cell lysis) in bacterial lawns and to be propagated as infectious agents.^{47,180} The first ~20 years of research on phages was aimed at understanding the basis of these phenomena, and in the process these studies contributed to developing ideas about the nature of viruses more generally. There was also keen interest during this time in phage therapy, the idea of using phages as agents to combat bacterial infections in human patients.¹⁷³ The “modern” era of phage research began in about 1940 when a diverse group of physicists and biologists who shared an interest in understanding the nature of the gene began to use phages as their experimental model system in this quest. This approach was wildly successful, playing a dominant role in the development of the field of molecular biology and leading over a period of ~35 years to much of our current understanding of not only the nature of the gene but also the ways that the information in genes is expressed and how that expression is regulated. Along the way, work on phages also made fundamental contributions to the field of virology. Phage research during this time was concentrated on a small number of phages, with the result that we now have a very deep understanding of a handful of individual phages. A crowning achievement of this era of phage-dominated molecular biology was the development in the early 1970s of the methods of recombinant DNA. This made many of the overwhelming technical advantages of phages as experimental

systems available for other organisms, including eukaryotes, and the center of gravity of molecular biology research shifted away from phages, though important basic research on phage life cycles has continued to the present. In recent years new themes have come to the fore in phage research that relate to natural phage populations and their effects on the environment and to phage evolution, including the influence of the phage population and its evolution on the evolution of their host bacteria.⁴⁹ These studies are inspired and made rational by the numbers cited in the first paragraph of this chapter, and they are made possible by the development of high-throughput sequencing technology and by the availability of the detailed knowledge of the biology of phages developed over the past 70 years.⁷² Studies on the assembly and structure of phage virions have had a central role in structural virology and have given insight into biological structure and assembly more generally.⁸⁸ Finally, throughout the history of phage biology there has been interest in the application of phages and their components to practical problems, and this has continued to the present, including but certainly not limited to a renewed interest in phage therapy.⁷¹

This chapter will first consider the main features of the life cycles of the different groups of phages that have been identified, essentially summarizing the detailed studies of individual “model” phages with an emphasis on what general principles of viral lifestyle are illustrated by each. For some of these, particularly the dsDNA tailed phages, there are enough examples of different phages in the group that we can begin to identify which features of the life cycles are universal among the group and which are either “optional” or accomplished by different mechanisms by different phages. We will then consider questions about phage populations and phage evolution—questions that are informed by the very large numbers cited in the first paragraph of this chapter.

Known bacteriophages have been divided into 10 families in the taxonomy of the International Committee on the Taxonomy of Viruses (ICTV)³ (Table 75.1). Three of these are somewhat arbitrary divisions (based on tail morphology) of the order *Caudovirales*, the dsDNA tailed phages. The other seven families each encompass a group of viruses with

common ancestry apparently shared among the group but not shared between the groups. In that phylogenetic sense the *Caudovirales* order and each of the other seven families can be regarded as parallel categories and roughly equivalent to the families defined for viruses with eukaryotic hosts. Nonetheless, the tailed phages (*Caudovirales*) are special in the sense that they are likely the numerically most abundant group of viruses on the planet and almost certainly the most genetically diverse. They are also the most extensively studied group of phages and so will occupy most of the space in what follows.

CAUDOVIRALES: dsDNA TAILED PHAGES

The dsDNA tailed phages are tremendously diverse genetically, to the extent that a majority of the protein sequences encoded in a newly determined phage genome sequence typically fail to make any matches in a database search.^{32,72} Genome sizes of known tailed phages range from a low of less than 19 kilobase pairs (kbp) up to just under 500 kbp, a range of more than 25-fold.⁷⁵ As will become evident, they are also very diverse in the specifics of their life cycles, including how they interact with the host cell. On the other hand, the similarities these viruses share across this range of diversity are so extensive as to leave no doubt that they share (distant) common ancestry, at least for the genetic features like the capsid protein genes that they all have.⁸⁰

The head of a tailed phage consists of a protein shell based on icosahedral symmetry that is usually a rather straightforward manifestation of the principles of capsid structure described by Caspar and Klug.³⁷ There is no lipid membrane. Replicated dsDNA is pumped into the empty protein shell through a 12-subunit grommet-like structure at one vertex of the icosahedral shell, known as the *portal*, or sometimes the *connector*. DNA is packaged in these viruses to an unusually high density, roughly the same as the density in a DNA crystal.¹⁰¹ Following DNA packaging, the portal, together with some adaptor proteins, serves as the attachment point for the tail.¹⁴⁷ The morphology of the tail is quite variable among different tailed phages, but it always has the same functions, namely, to attach to the surface of the host cell and serve as a conduit for delivering the DNA into the cytoplasm of the cell. The bulk of the virion protein is left on the outside of the cell after DNA injection, a circumstance that made possible the classical Hershey/Chase experiment⁸¹ that showed that the genetic material is DNA and not protein. Once the DNA arrives in the cytoplasm, the genetic diversity among different phages alluded to earlier is manifested as diversity in the details of their life cycles, and specific examples of the life cycles of a few well-studied phages are given later. At a fundamental level, these phages can be divided into “virulent” and “temperate” categories. Virulent phages always enter the lytic life cycle, in which infection always leads to production of progeny virions and their release by cell lysis, with cell death. Temperate phages, in contrast, make a “choice” soon after infection between lytic growth and entering the lysogenic cycle, in which gene expression from the phage DNA is largely repressed and the phage becomes a part of the genetic complement of the host cell—now called a *prophage*—and

TABLE 75.1 ICTV-Designated Phage Families

Family	Prototypes	Characteristics
<i>Siphoviridae</i>	λ	dsDNA, long, noncontractile tails
<i>Myoviridae</i>	T4	dsDNA, contractile tails
<i>Podoviridae</i>	T7	dsDNA, short, stubby tails
<i>Tectiviridae</i>	PRD1	dsDNA, linear 5' proteins, internal membrane
<i>Microviridae</i>	ϕ X174	ssDNA, circular, icosahedral
<i>Inoviridae</i>	M13	ssDNA, filamentous
<i>Leviviridae</i>	MS2, Q β	ssRNA, small icosahedral
<i>Cystoviridae</i>	ϕ 6	dsRNA, segmented, enveloped
<i>Corticoviridae</i>	PM2	dsDNA, circular, internal membrane
<i>Plasmaviridae</i>	L2	dsDNA, circular, enveloped

dsDNA, double-stranded DNA; ssDNA, single-stranded DNA.

replicates as part of the cellular DNA without killing the cell for an indefinite number of generations.

In the following sections we consider in moderate detail the life cycles of two very well-studied tailed phages, λ and T4, both phages of *Escherichia coli* and possibly the most extensively studied viruses of any kind. These two have served as important model experimental systems since the 1940s and 1950s. They were the initial source of much of our understanding about the nature of tailed phages, and their numerous differences highlight the diversity seen among the well-studied tailed phages. There are numerous other tailed phages that have made similarly important contributions to our understanding, and we have chosen several of them to illustrate features of their life cycles that are not represented in the two phages that are discussed in detail. Some of the topics considered here have been the subjects of intensive study by multiple investigators for 50 years or more, and in such cases it may not be possible to cite all the relevant primary literature; if so, useful reviews will be cited that give access to the primary literature.

Bacteriophage λ and the “Lambdoid” Phages

The K12 strain of *E. coli* was isolated from a pediatric patient at Stanford University Hospital in 1922. Some 30 years later, in the course of bacterial genetics experiments with K12, Lederberg and Lederberg¹⁰⁵ discovered a temperate phage that was carried as a prophage in the K12 genome, which they named λ . Phage λ subsequently became the most extensively studied of a small number of temperate phages that were chosen for experimental investigation. Other phages that are similar to λ in gene organization and lifestyle, and which can form recombinants with λ at reasonably high frequency, have been

termed *lambdoid* phages.²⁶ Some of the lambdoid phages have been studied in their own right, and all of them and their hybrids with λ have had an important role in illuminating some of the most fundamental aspects of the temperate phage lifestyle.⁷⁷

Phage λ 's dsDNA genome is 48,503 bp in length (Fig. 75.1).^{78,164} The DNA molecule in the virion has its ends at discrete sequences, and there are 12 base single-stranded 5' extensions at the ends. The extensions are complementary in sequence, allowing the linear molecule to circularize by base pairing between these “cohesive ends,” which it does immediately upon being injected into the host cell. The two joined ends are then covalently joined by the host enzyme, DNA ligase.¹⁹⁵

The λ virion has an isometric head (capsid) with T = 7 icosahedral symmetry and a long noncontractile tail (Fig. 75.2). It infects its *E. coli* host by binding to the surface of the cell first through its long “side tail fibers,” which bind to the outer membrane protein OmpC, and then through an interaction between the host outer membrane protein, LamB, and the phage protein, gpJ, located at the tip of the tail.¹⁸⁹ Only this second interaction (gpJ:LamB) is essential for successful infection; the side tail fibers, which make adsorption kinetics faster, were lost through a mutation early in the laboratory history of λ .⁷⁸ (Note on nomenclature: in the phage literature, gpX refers to the protein encoded by gene X, with “gp” meaning “gene product” and *not* “glycoprotein.”) Details of the DNA injection process are not well understood but are thought to include a rearrangement of some of the proteins that make up the tail tip to facilitate passage across the cell envelope, a process for which there is experimental support in some other phages but not yet in λ . One thing that must

FIGURE 75.1. Map of the phage λ genome. λ DNA is represented as the red bar with genes shown as boxes above; functions are indicated.

FIGURE 75.2. The bacteriophage λ virion. Electron micrograph of λ , negatively stained with uranyl acetate. Scale: the length of the tail, excluding fibers, is ~ 150 nm. (Courtesy of Robert Duda.)

happen before the DNA can pass out of the head, down the tail tube, and into the cell is that the tail length tape measure protein, gpH, a few copies of which occupy much of the lumen of the tail, must exit. There is biochemical evidence that gpH is injected into membrane vesicles if the membranes contain the LamB receptor protein,¹⁵⁸ and there is genetic evidence that gpH must interact with an inner membrane sugar transport protein, PtsM, in order for injection to be accomplished successfully.¹⁵⁷

Following DNA injection and circularization, λ makes a decision between the lytic and lysogenic life cycles. We first describe the lytic cycle, in which the phage programs the cell to produce a crop of progeny virions and releases them by cell lysis at the end of the growth cycle. Following that, we describe the lysogenic cycle, in which the expression of most phage genes is repressed and the phage DNA integrates into the continuity of the host chromosome as a prophage.

The Lytic Cycle

All transcription of λ genes is carried out by the host RNA polymerase, unmodified for immediate early transcription and altered in its properties by interaction with phage-encoded proteins for subsequent temporal classes of transcripts.⁶⁶ The genes are generally arranged in large operons, making it possible to regulate their transcription by regulating a small number of promoters. Upon DNA entry, RNA polymerase initiates transcription at the two divergent immediate early promoters, P_L and P_R , completing transcription of just one gene in each case, gene *N* and gene *cro*, respectively, before encountering a ρ -dependent terminator and stopping.¹³³ The N protein, gpN, is a transcription antitermination factor that renders polymerase insensitive to termination signals by forming a complex with polymerase, several host factors, and a specific signal near the start of

the nascent transcript called *nut*, for Nutilization. The RNA polymerase, altered in this fashion, now reads through the terminators and into early genes farther down the P_L and P_R controlled operons. The most relevant of these genes for the lytic cycle are the *O* and *P* genes, which mediate phage-specific DNA replication, and the *Q* gene, which has a central role in mediating late gene transcription, all transcribed from the P_R promoter, and three genes for recombination enzymes, transcribed from P_L .⁴⁵ An important feature of the *nut* sites is that they only act *in cis*—that is, gpN can cause antitermination only for a polymerase that starts from a promoter with a *nut* site near the beginning of the transcript, which in λ means only P_L and P_R . A consequence of this is that some transcribing polymerases can be insensitive to termination signals at the same time that others are susceptible to termination, depending on which promoter they started at. This differential sensitivity to termination signals figures in the regulation of the proteins responsible for integration and excision of the prophage, described later.

Transcription of the late genes starts about 10 minutes after the start of infection, from the P_R' promoter located downstream from the *Q* gene (Fig. 75.1). The P_R' promoter is a strong promoter, recognized by the unmodified host RNA polymerase, but the polymerase requires the action of the early phage protein gpQ to read through a strong pause site located soon after the promoter.¹⁵⁵ As with polymerase that has been acted on by gpN, polymerase acted on by gpQ is insensitive to termination signals and reads through the entire ~ 26 -kb late gene operon, which includes the lysis genes, head genes, and tail and tail fiber genes. Despite the fact that all of the late genes are transcribed equally, the molar amounts of the proteins produced by translation of the messenger RNA (mRNA) vary more than 1,000-fold due to differences in efficiency of translation initiation.³⁴ The amounts of the proteins produced appear to be appropriate to what is required for efficient assembly of virions.

Phage DNA replication is carried out by the host replication machinery, but that machinery is directed to the phage replication origin by two phage-encoded early proteins, gpO and gpP. gpO binds to the origin, four tandem imperfect 19-bp repeats within the gene *O* coding region, to form a compact complex to which gpP binds.¹⁸⁸ gpP recruits the host replication helicase, DnaB, to the complex; the rest of the host replication machinery joins; and gpO and gpP are removed by the host chaperones, DnaK, DnaJ, and GrpE, which allows the replication complex to start replication.¹⁴³ Replication is initially bidirectional, producing more unit-length circles by a “theta” mode of replication, but at 10 to 12 minutes after infection it shifts to a unidirectional rolling circle mode to produce the multigenome concatemer that is the DNA substrate for packaging into heads.

The heads and tails of phage λ are assembled separately and join to form virions after their assembly is complete.⁷³ Purified heads and tails will join efficiently *in vitro* to make infectious virions, implying that no additional factors are required for this step of assembly. Tail assembly starts with a complex of the proteins that will form the tip (head-distal) end of the tail. The initial complex is joined by a few copies of the *tape measure protein*, gpH, which extends the length of the tail as an α -helix and provides a template around which

the major tail protein, gpV, polymerizes as 32 stacked rings of 6 subunits each.⁹² This polymerization is thought to be mediated by two proteins, gpG and gpGT, which are essential for assembly but absent from the mature tail, and which are therefore regarded as tail assembly chaperones. The two chaperones are produced as the result of an inefficient translational frameshift between two overlapping open reading frames, an arrangement that is highly conserved among other long-tailed phages.¹⁹⁶ Following assembly of the tail tube, two adaptor proteins add to the top of the tail and it is ready to join to a head.

As with all other characterized tailed phages, λ head assembly first produces an empty protein shell—the prohead or procapsid—into which DNA is packaged. Four phage-encoded proteins participate in prohead assembly; the major capsid protein, gpE; the portal protein, gpB; the protease, gpC; and the scaffolding protein, gpNu3.³⁸ The details of how these proteins come together to assemble accurately into a $T = 7$ capsid are not entirely clear, but the assembly is thought to be nucleated by the portal, a 12-subunit grommet-like structure that occupies one vertex of the otherwise icosahedrally symmetric prohead.¹⁴⁷ Assembly of the major capsid (coat) protein requires the participation of similar numbers of the scaffolding protein. How the scaffolding protein contributes to this process remains the central mystery of how capsid assembly is achieved. In the absence of scaffolding protein, the capsid protein assembles into “monsters,” sheets, tubes, and misshapen spirals of capsid protein that have apparently lost the ability to insert pentamer vertices into the hexagonal lattice of capsid proteins with sufficient accuracy and regularity to make an isometric, icosahedrally symmetric structure.

Roughly 10 copies of the protease are assembled into the prohead, and these are responsible for cutting the scaffolding protein into fragments that are lost from the structure. The portal subunit is also proteolytically processed, with 22 amino acids removed from the N-terminus, but unlike what is observed in some phages, the major capsid protein is not processed. The protease itself participates in a curious “protein fusion” reaction, in which a portion of each protease molecule is joined covalently to a copy of the major capsid protein.¹²⁰ Following, or concomitant with, the proteolytic maturation of the prohead, DNA packaging commences. DNA is pumped into the procapsid through the ring of portal protein subunits by a phage-encoded, adenosine triphosphate (ATP) cleavage-powered DNA translocase similar to that of phages T4 and $\phi 29$ (see later). This molecular motor also contains the nuclease that cleaves *cos* sites to release the packaged DNA from the concatemer that is the substrate for packaging.

Progeny λ particles are released from the cell through a tightly controlled lysis system that ensures the concluding act of lytic growth occurs at the optimal time.¹⁸⁶ λ lysis requires the products of four genes, *S*, *R*, *Rz*, and *RzI*. gpR is the endolysin and cleaves the peptidoglycan layer in the cell wall, but it has no effect on the integrity of the cell until it has access to its substrate, which is prevented by the cytoplasmic membrane. Access, and the timing of lysis, is determined by the products of gene *S*, the 105-residue holin (S105), and the 107-residue antiholin that is translated from an initiation site two codons upstream of that used for S105. The ratio of S105 and S107

is critical for the timing of lysis, which occurs when S105 produces one or more large-sized holes in the membrane.⁵⁴ Rz and RzI form a *spannin* complex that spans the periplasm and leads to fusion of the inner and outer membranes to ensure efficient and complete lysis.¹⁵

Lysogenic Cycle

The lysogenic cycle starts the same way as the lytic cycle described earlier, with DNA injection and circularization, transcription from P_L and P_R , extension of that transcription by the action of the gpN antitermination protein, and the consequent expression of the early proteins. Among these early proteins are CII (“C-two”), transcribed from P_R , and CIII (“C-three”), transcribed from P_L .⁴⁵

The CII protein plays the central role in the “decision” between the lytic and lysogenic cycles. CII is a transcription factor that binds to and activates the leftward-pointing promoter P_{RE} (*promoter for repressor establishment*). The resulting transcription from P_{RE} goes backward through the *cro* gene and then forward through the leftward-oriented *cI* gene, causing production of the λ repressor, the CI (*C-one*) protein. When it is produced in sufficient quantity, the CI repressor shuts off further transcription from P_L and P_R by binding to the overlapping operators, O_L and O_R , respectively, and occluding the promoters from RNA polymerase binding. In this way repression is established and can persist for an indefinite number of bacterial generations.

The choice between the lytic and lysogenic cycles is determined by the level of CII protein in the infected cell—with enough CII, transcription from P_{RE} is activated sufficiently to produce enough CI repressor to establish repression, while with low levels of CII, too little CI repressor is made to stop transcription from P_L and P_R , and the lytic cycle goes forward as described earlier. The level of CII protein is determined in turn by environmental factors, principally the physiologic state of the infected cell. The readout of the state of the cell is the level of a cellular protease, FtsH, which degrades CII, and is modulated by HflKC and cyclic adenosine monophosphate (cAMP).⁹³ In this sense, CII is the sensor with which the phage assesses the state of the cell and decides between the lytic and lysogenic cycles. Another phage protein, CIII, biases the decision in favor of lysogeny by antagonizing the FtsH protease and disfavoring degradation of CII protein.⁹⁵ Finally, a high multiplicity of infection favors lysogeny; this is thought to be because a larger number of genomes in the cell means higher production of CII and CIII proteins. More recently, it has been shown that λ preferentially binds to the cell poles—especially at the low multiplicities of infection favoring lytic growth—where FtsH is also localized, suggesting there is a topologic component to the lytic/lysogenic decision.⁵⁸

Once lysogeny is established, expression of the CI repressor maintains the prophage state (Fig. 75.3). CI binds to two tripartite operator sites, O_L and O_R , to repress the early lytic promoters, P_L and P_R , respectively.¹⁰⁹ However, CI also plays an important role in regulating its own expression, acting as an activator of the promoter for repressor maintenance (P_{RM}) when bound to the O_{R1} and O_{R2} sites in O_R , and as a repressor when concentrations are sufficiently high to permit binding to the weaker site, O_{R3} . An important component to

FIGURE 75.3. DNA looping by the λ repressor. Models of CI regulation by DNA looping. Detailed conformations of the structures are not known and maps are not drawn to scale. **A:** Promoters (P_R , P_L , and P_{RM}); operators O_L (O_{L1} , O_{L2} , O_{L3}) and O_R (O_{R1} , O_{R2} , O_{R3}) are in blue rectangles; CI dimers (one monomer is shown in yellow, the other in gray). The bent arrows show the transcription start points of promoters. The dashed line indicates transcripts from P_R , P_L , and P_{RM} . The *cl* gene is transcribed from P_{RM} . **B:** DNA looping and octamer formation (8-mer) by CI tetramer binding to O_{L1} ~ O_{L2} interacts with that at O_{R1} ~ O_{R2} . **C:** Octamer and tetramer (12-mer) of CI binding to O_L and O_R . Red X means promoter is turned off. (From Lewis D, Le P, Zurla C, et al. Multilevel autoregulation of lambda repressor protein CI by DNA looping in vitro. *Proc Natl Acad Sci U S A* 2011; 108:14807–14812, with permission.)

repression is the formation of DNA loops formed by cooperative association of repressor tetramers bound at O_{L1} and O_{L2} , and at O_{R1} and O_{R2} ; this looping also stimulates activation of P_{RM} .⁵ Additional cooperative interactions between O_{R3} and O_{L3} enhance the repression of P_{RM} at high repressor concentrations.¹⁰⁹

The DNA replication genes of a λ prophage are repressed by the action of the CI repressor protein, and the prophage relies on the host replication functions for maintenance in the population as the cell grows and divides. To take advantage of these replication services, the prophage DNA must be integrated into (becomes part of) the host chromosome where it is replicated along with all the other host genes (Fig. 75.4). Integration is catalyzed by the phage-encoded integrase protein (Int), which carries out site-specific, reciprocal recombination between a site on the phage DNA, *attP* (attachment site, phage), and a site on the bacterial chromosome, *attB* (attachment site, bacterium). Because the phage DNA is at this point circular, having joined its cohesive ends immediately upon injection, the Int-mediated reciprocal recombination results in the insertion of a linear form of the phage DNA into the bacterial chromosome. Because the *attP* site, where the phage DNA is broken upon integration, is distant from the *cos* (cohesive ends) site, where the virion DNA was joined, the order of genes in the integrated prophage is a circular permutation of the gene order in the virion DNA. This mechanism of prophage integration, generally known as the *Campbell Model*, seems rather straightforward now; when it was proposed in 1962 by Allan Campbell (the author of this chapter in the previous edition), it was a major conceptual breakthrough.²⁷

The *attP* site has a 15-bp “core” sequence that is identical to the corresponding core sequence in *attB*, and it is within the core sequence that the strand exchanges of recombination take place.¹⁰² *AttP* extends on both sides of the core sequence and requires ~240 bp in total. These flanking sequences contain binding sites for Int; for integration host factor (IHF), a host-encoded DNA binding/bending protein; and for Xis and Fis (see later). The *attB* site is only 30 bp long, having fewer such binding sites flanking its core sequence.¹⁰² Integrative recombination takes place within a synaptic complex formed when an *attP*-intasome—containing Int and IHF—captures *attB* DNA.¹⁵³ The reaction proceeds with cleavage of the “top” strands of the two attachment sites by Int and reattaching them to the cut strand of the opposite *att* site to form a Holliday junction.¹⁰² The energy of the phosphodiester bond is preserved by two successive transesterifications, first to the active site tyrosine of the integrase and then to the recipient DNA strand, and no additional chemical energy is needed to drive the reaction. Following the top-strand exchange, the complex branch migrates by 7 bp, and bottom-strand exchange takes place by the same mechanism. The reaction product is an integrated prophage flanked by two hybrid attachment sites, *attL* and *attR*.

The lysogenic “cycle” is completed when, after an indefinite number of generations as a repressed prophage, the prophage enters the lytic cycle by the process known as induction. The proximate cause of induction is loss of repression. Induction occurs in about one cell in 10^4 to 10^6 in a culture of lysogenic cells under laboratory conditions (*spontaneous induction*), but it occurs in nearly 100% of the cells in the culture when they are activated by a moderate dose of ultraviolet light or similar DNA damaging agent. Such treatment causes high production of the cell’s RecA protein, which when bound to single-stranded DNA (ssDNA) causes the CI repressor to undergo an autoproteolytic cleavage. This cleavage separates the protein’s dimerization domain from its operator-binding domain,⁴⁶ and as monomers, the CI operator-binding domains do not have a high enough affinity for their operators to block transcription from P_L and P_R , and so the lytic cycle begins.

An essential part of λ prophage induction is the detachment of the prophage from the host chromosome, termed *excision*. Macroscopically, excision is the reverse of integration—that is, the *attL* and *attR* sites at the ends of the prophage undergo reciprocal recombination to release the circular phage DNA molecule. Excisive recombination requires two protein factors in addition to the Int and IHF needed for integration, namely, the host DNA binding/bending protein Fis and the phage-coded Xis (pronounced “excise”) protein. Together, these four proteins and the *attL* and *attR* sites form the excision complex.

Both integration and excision require the catalytic action of integrase, but whether the reaction goes in the direction of integration or excision depends on the absence or presence of Xis (Fig. 75.4). Accordingly, the amount of Xis is differentially regulated by a mechanism that senses whether or not the phage DNA is integrated; if integrated, both Int and Xis are made, allowing excision, and if not, only Int is made, allowing integration. The crucial regulatory site is a sequence named *sib*, located downstream from and across *attP* from the *int* and

FIGURE 75.4. Insertion of λ DNA into the bacterial chromosome. λ virions contain linear DNA with short single-stranded cohesive ends that are ligated to circularize the genome following injection into the cell. *attP* is located near the center of the genome and the order of some of the genes (A, B, C, etc.) is shown. A prophage is formed by site-specific recombination between the phage attachment site (*attP*) and the bacteria attachment site (*attB*), which is catalyzed by the phage-encoded integrase but also requires integration host factor (IHF). Prophage excision occurs only in the presence of the phage-encoded Xis, which redirects integrase to recombine the attachment junctions *attL* and *attR* to re-create *attP* and *attB*. The virion structure and assembly genes are typically represented as forming the left arm (between *cos* and *attP*) in the viral genome but are permuted relative to the right arm (between *attP* and *cos*) in the prophage.

xis genes.¹¹⁷ *Sib* has the effect of destabilizing mRNA transcribed from P_L (antiterminated by gpN), which includes the sequences of both *xis* and *int*, but it does not destabilize mRNA from P_i , a CII-dependent promoter within the *xis* coding sequence that encodes only Int. Thus, when *sib* is downstream from *xis* and *int*—that is, when the phage DNA is not integrated—only Int protein can be made and so (provided sufficient CII is made to activate P_i and the phage is headed into the lysogenic cycle) integration ensues. In the integrated prophage, on the other hand, *sib* is no longer downstream from *xis* and *int*, as a result of the integrative recombination. When the prophage is induced, the transcript from P_L , encoding both Xis and Int, is not destabilized, so both proteins are made and excision occurs. Perhaps surprisingly, this elegant and efficient mechanism has been seen only in λ and a few of its closest relatives; there appears to be a great variety of different pathways for achieving the appropriate regulation of prophage integration and excision that have evolved in different temperate phages.

Bacteriophage T4

Bacteriophage T4 is one of seven “type” phages isolated by Delbrück in the 1930s and 1940s that he declared warranted further study.²⁵ It has received considerable attention from that time to the current day and continues to be a source

of new insights into virology, molecular biology, and structural biology. It is virulent and reproduces quickly (less than 30 minutes), and particles with prolate (i.e., elongated) heads and contractile tails contain a dsDNA genome of ~170 kb (Fig. 75.5). T4 is not alone in the biosphere, and many phages with similar features have been identified, including two other Delbrück “type” phages, T2 and T6, and phages of other *Proteobacteria* and of the *Cyanobacteria*. These contain genomes ranging from 160 kbp to 250 kbp and range from those with close DNA similarity to T4 to those much more distantly related. Although these relatives contain a “core genome” of about 12% to 15% of T4 that are typical of this group, they are otherwise mosaic with common segments interspersed with unrelated genes.¹⁴⁰ Although we will focus here on T4 as the most intensively studied of these, many of the other T4-like phages are likely to share much of its biology.

T4 Genome

The T4 genome contains a unique sequence of 169,903 bp, and virion genomes are circularly permuted with terminal redundancies of ~5,000 bp¹²⁴ (Fig. 75.5). It codes for 160 proteins with known functions, as well as about 120 open reading frames (ORFs) with unknown functions, and several small RNAs, including 8 transfer RNAs (tRNAs). Some parts of the

GENOMIC MAP OF BACTERIOPHAGE T4

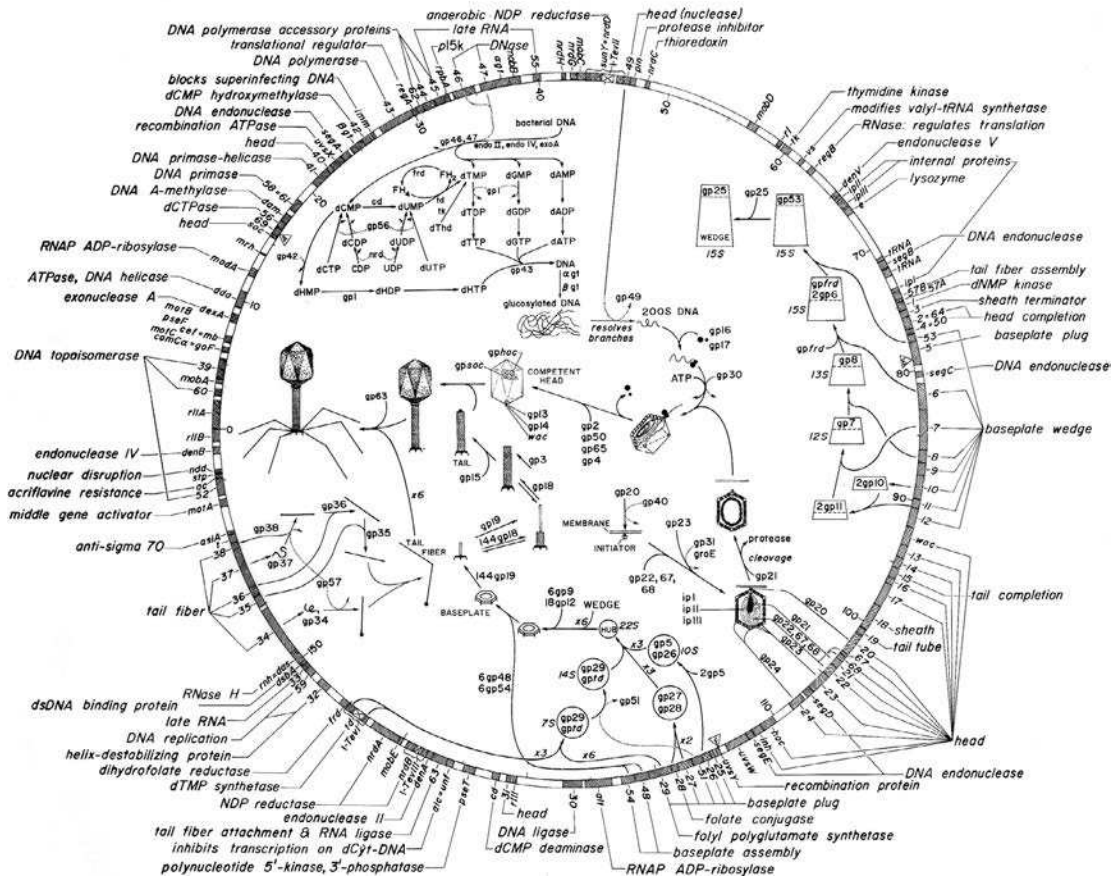

FIGURE 75.5. Genomic map of phage T4. The T4 genetic map is circular rather than linear because of the circular permutation of T4 phage chromosomes due to its headful packaging from long concatemers. The general structure of the map was established by standard genetic techniques using classical markers such as those affecting plaque morphology, as well as *amber* mutations that were used to identify many genes. This map shows many of the known and all of the essential genes, based on that classical mapping work and on genome sequence data; the small numbers just inside the circle show the coordinates of the genomic map in kilobase pairs. The names and functions of many genes and the grouping of genes into clusters of related function are shown on the periphery. The branched assembly map in the center shows how an efficient complex of enzymes is produced to make the deoxynucleotides and feed them directly into the T4 DNA polymerase complex (**upper left region**) as well as the branched virion assembly pathway, illustrating how components made in the various branches of the pathway merge to produce an infectious bacteriophage. The small numbers just inside the circle show the coordinates of the genomic map in kilobase pairs. This version of the T4 assembly genomic map is a reduction of a 3-foot-wide hand-drawn map representing an icon in bacteriophage biology. (Courtesy of B. Guttman and E. Kutter. Modified from Karam JD, Kreuzer KN, Hal DH. *The Molecular Biology of Bacteriophage T4*. Washington, DC: ASM Press, 1994, with permission.)

genome are predicted to be mobile, and there are at least 15 homing endonucleases, 3 of which are within introns.⁵⁹ T4 DNA is somewhat unusual in that it contains glucosylated hydroxymethylcytosine (hmC), which protects it from host restriction systems and distinguishes it from host DNA that can be degraded and utilized for phage replication.

Expression and Regulation

Expression of T4 genes follows an orderly series of temporally controlled patterns, all involving the use of the host RNA polymerase.⁸² However, a complex series of both covalent and noncovalent modifications to RNA polymerase are required to successfully orchestrate this transcriptional ballet. Transcription of the first T4 genes involves recognition of promoters resembling strong host promoters by σ^{70} -associated

host RNA polymerase, but two phage-encoded early products make important modifications to the RNA polymerase. Alt (a protein that is injected with the DNA into the infected cell) catalyzes adenosine diphosphate (ADP) ribosylation of one α subunit of RNA polymerase, improving the activity of certain T4 early promoters. Two other T4 proteins, ModA and ModB, also ADP-ribosylate RNA polymerase or proteins used in translation during early stages of infection. Another protein, Alc, leads RNA polymerase to selectively terminate transcription prematurely on the host dC-containing DNA while ignoring the viral hmC DNA.⁸² As a consequence of these events, transcription of T4 genes readily outcompetes that of the host, with a strong burst of activity within the first minute of infection. The functions of many of these early genes are not known, but two early products, MotA and AsiA, play important

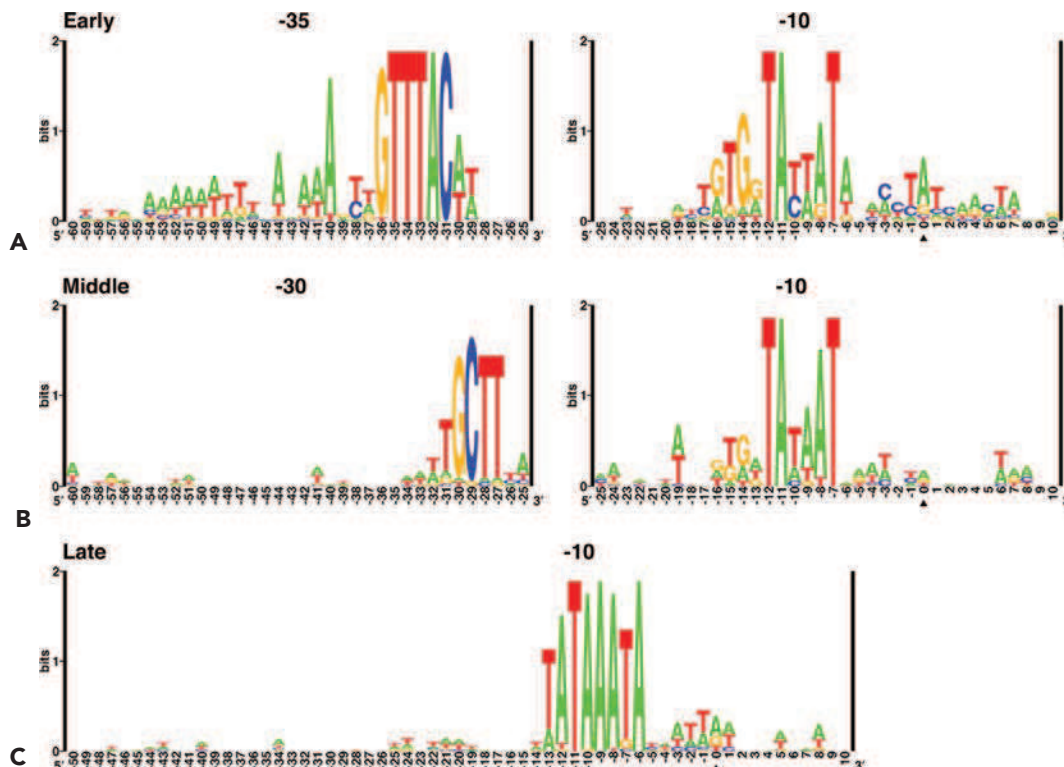

FIGURE 75.6. Logo of T4 promoters. Nearly all the sequences in each alignment have promoter activity, as demonstrated by primer extension, transcription from cloned DNA fragments, or RNA hybridization assays. Those promoters included whose start sites have not been mapped all precede a corresponding early, middle, or late gene and show significant similarity to the relevant promoter class. Sequences were independently aligned in the -10, -30, or -35 regions. The information content (Rs) is calculated in “bits” and is the sum of the Rs for each region (except for the late logo, which was calculated from the single alignment at -10). Alignments, logos, and Rs values were obtained as described elsewhere ((966) and E. Miller, T. Dean, and T. Schneider, unpublished data). The triangle marks the +1 transcription start site. **A:** Thirty-nine early promoters, Rs = 38.3 bits. **B:** Thirty middle promoters, Rs = 21.1 bits. **C:** Fifty late promoters, Rs = 16.2 bits. (From Miller ES, Kutter E, Mosig G, et al. Bacteriophage T4 genome. *Microbiol Mol Biol Rev* 2003;67:86–156, with permission from the American Society for Microbiology.)

roles in the transition from early to middle transcription. Many early T4 mRNAs also disappear quickly at the end of the early phase, largely through the action of RegB, an endoribonuclease that targets early gene transcripts.

MotA is a transcriptional activator that functions along with a co-activator, AsiA, to redirect transcription toward T4 middle promoters. The middle period genes primarily encode functions for DNA metabolism and DNA replication, including *denA* and *denB*, that encode the functions for degrading dC-containing host DNA. About 60 middle promoters have been identified, which contain a host-like -10 sequence (Fig. 75.6) and a MotA box at position -30. MotA binds somewhat weakly to its DNA site but associates strongly with σ^{70} . The co-activator AsiA plays an important role in the transition by also binding to the σ^{70} subunit of RNA polymerase and conformationally altering the helix-turn-helix DNA binding motif within region 4. As a consequence, recognition of promoter -35 sequences is interrupted (an “antisigma” activity), reducing transcription from both host and T4 early promoters. Thus, MotA and AsiA collaborate to effectively direct the host σ^{70} to initiate transcription at the unique promoters preceding T4 middle genes.

The transition from early to middle gene expression is also mediated by extension of early T4 transcripts, as many middle

genes lie immediately downstream of early genes (Fig. 75.6). Termination of the early transcripts likely occurs at Rho-dependent sites; however, readthrough or antitermination at these sites can give rise to some middle gene expression. However, the antitermination mechanism is unclear. The process could involve an as yet unidentified antiterminator factor (equivalent to λ N or Q; see earlier) or could simply be the consequence of transcription and translational coupling, such as seen when closely linked genes in bacterial operons overcome genetic polarity.⁸²

The transition from middle to late T4 gene expression requires the products of genes 33 and 55.⁶⁵ T4 gp55 is a highly divergent member of the σ^{70} group of proteins and associates with host RNA polymerase to redirect it toward late promoters, which are characterized by an eight-base pair TATA box (5'-TATAAATA-3') at the position where the -10 site is usually located (Fig. 75.6). There are about 50 related sites in the T4 genome, and many are used to direct late transcription. T4 gp33 binds to the flap tip of the RNA polymerase β subunit, which usually interacts with the region 4 of σ^{70} such that gp33 mimics this association. T4 gp33 does not recognize a specific DNA sequence (there is no -35 region in T4 late promoters), but it may function by diminishing nonspecific DNA interaction, thus increasing the specific affinity of gp55–RNA polymerase for T4 late promoters.⁶⁵

Interestingly, there is a close linkage between T4 late transcription and DNA replication. T4 gp45, the sliding clamp processivity factor for DNA replication, is strongly implicated in late transcription. It forms “split rings” that load onto DNA with a particular polarity (depending on how the DNA is nicked) and track along the DNA. T4 gp45 and the late transcription factor gp55 associate such that the sliding clamp facilitates the search for promoters. gp33 is also required for replication-activated transcription at T4 late promoters.

Studies on T4 gene expression also contributed many seminal findings in the area of postranscriptional control. These include the identification or discovery of translational stop codons, discovery of suppressor tRNAs, tRNA cleavage and subsequent repair by polynucleotide kinase and RNA ligase, protein-mediated translational repression, and group I autocatalytic introns (“ribozymes”). Details of these processes in T4 and T4-related phages are reviewed in Edgell et al.⁵⁹ and Uzan and Miller.¹⁸²

Genome Replication

Soon after T4 infection, synthesis of DenA and DenB targets host DNA for degradation to mononucleotides, followed by subsequent conversion of deoxycytidine monophosphate to deoxyhydroxymethylcytosine monophosphate. This is incorporated into T4 DNA during its replication, and the deoxyhydroxymethyl cytosines are subsequently modified by glucosyltransferases. A T4-encoded deoxycytidine-triphosphatase (dCTPase) keeps deoxycytidine-triphosphate (dCTP) levels low, so that dCTP does not get errantly incorporated into the newly synthesized T4 genomes. DNA replication occurs in two distinct modes, one that is origin dependent and one that is recombination dependent.

T4 DNA replication is bidirectional and initiates at as many as seven major origins of replication (*oriAi* through *oriG*) early in infection.⁹⁷ Initiation requires assembly of a replisome containing several T4 proteins (DNA polymerase, sliding clamp loader, sliding clamp, helicase, primase, and SSB) and synthesis of primers by the host RNA polymerase (to form R-loops). RNA primers can arise from the MotA-dependent promoters at the *ori* sites, and for the lagging strand, from the activity of the T4 primase, gp61. These primers are processed by a phage-encoded RNase H. Coordinated leading- and lagging-strand synthesis then proceeds through to the ends of the viral DNA, generating 3' extensions (because of the inability to prime synthesis at the extreme 5' ends of the genomes). Subsequent reprogramming of the host RNA polymerase specificity (see earlier) results in the cessation of this early mode of DNA replication, and a late-expressed protein, UvsW, actively unwinds the RNA–DNA hybrids used for initiation.⁵⁶

The second, late mode of T4 DNA replication is characterized by the dominant role played by homologous recombination and is known as recombination-dependent replication (RDR). The genome ends generated by early (origin-dependent) replication are good substrates and can engage in recombinational pairing with other (co-infecting) genomes or with the other end of the same genome because of the terminal redundancy. Genetic studies suggest that there are multiple pathways by which RDR can proceed, but the primary mode is the formation of D-loops by invasion of an ssDNA end into a DNA duplex, followed either by semiconservative synthesis or synthesis with branch migration.⁹⁷ Several T4 proteins are involved in RDR, including UvsX (a RecA-like protein), gp32 (ssDNA

binding protein), UvsY (which loads UvsX onto gp32-coated DNA), UvsW (a helicase involved in strand invasion and branch migration), gp59 (for loading the helicase), and the replisome complex. The structures of several of these components have been described.¹²⁹ Overall, multiple pathways involving several different phage-encoded enzymes ensure effective replication of the genome. These pathways do not function entirely independently of one another, and thus the T4 system has allowed detailed study of genome replication, recombination, and repair that is germane to both viral and cellular processes.

DNA Packaging

The products of T4 replication are branched, concatemeric networks of DNA in which individual molecules are not distinguishable.¹⁴⁶ Packaging of the DNA into capsids is initiated by the binding of the terminase small subunit protein gp16 to the viral DNA. The small terminase subunit binds as rings (probably 11-mers), and then the gp17 large terminase subunit associates with the protein–DNA complex. This complex associates with the 12-fold symmetric portal protein that sits at a position of one of the capsid pentamers (see later). This “packasome” also contains T4 gp49, a Holliday junction resolvase that removes DNA branches that are otherwise detrimental to packaging. gp17 has two important catalytic domains involved in DNA packaging: an N-terminal adenosine triphosphatase (ATPase) domain and a C-terminal endonuclease domain. Both functions are important for the translocation “motor” activity of the packaging system.

An attractive model for the packaging mechanism is the portal rotation model.⁷⁶ The symmetry mismatch between the 5-fold capsid and 12-fold portal means that only one subunit of each can align in any given register. Activation of the terminase ATPase activity could then lead to rotation of the portal and translocation of the DNA, as if a bolt were turning within a nut.¹⁴⁶ Although attractive, single-molecule experiments with the ϕ 29 packaging system (see later) argue against a portal rotation model,⁸⁶ other models include a terminase-driven packaging system in which cycles of ATP hydrolysis leads to DNA translocation.¹⁷⁴ Regardless of the mechanistic details, the T4 packaging motor is remarkably powerful when scaled to a macro level, being twice as powerful as a typical automobile engine.¹⁴⁶

Once packaging begins, the process continues until the capsid is full of densely packed dsDNA (~500 mg/mL)—typically about 103% of the unique genome content—at which point the nuclease activity of the large terminase subunit is triggered to cleave the DNA. Although the terminase–DNA complex dissociates from the filled capsid–portal complex, it may associate with another empty capsid to begin packaging of the DNA from the previous cleavage event. This *headful packaging* process can then continue for as many unit genome lengths present in the concatemer and is the basis for the circularly permuted, terminal redundancy found at the ends of the packaged genome in each virion.

Virion Structure and Assembly

The lunar-lander-shaped T4 virion is one of the most widely recognized icons of molecular biology, and its complex shape requires a correspondingly complex assembly strategy that uses premade subassemblies. These are capsids, tails, and tail fibers that are each made *via* independent pathways that do not merge until the subassemblies are joined together to make a complete virion after DNA packaging is complete. The general

outlines of T4 assembly were the result of decades of genetic, biochemical, and structural work. Our understanding of the structure and assembly of each of the subassemblies of the T4 virion has fortunately been enhanced in recent years through structural approaches, primarily cryoelectron microscopy (cryo-EM) and x-ray crystallography.^{63,106}

The mature T4 capsid is composed of 960 copies of the cleaved major capsid subunit, gp23*, and 55 copies of the cleaved capsid vertex protein, gp24*, both of which have the HK97-fold. The angular head is a $T = 13$, $Q = 21$ elongated icosahedron 86 nm wide by 120 nm long¹⁴⁶ and also contains about 1,000 molecules of proteolytically processed internal proteins. The capsid is made initially as a prohead composed of uncleaved proteins that are proteolytically processed only after all prohead components have been added, and after which the proteolytically processed proteins are denoted with a “*” (gp23 is converted to gp23*). Prohead assembly occurs at or around a scaffold core containing gp21 (protease), gp22, gp67, gp68 (scaffolding proteins), gpIPI, gpIPII, gpIPIII, and gpalt (internal proteins) that forms atop a cell membrane-bound portal complex made of gp20, which later is the site of DNA packaging and tail addition. The prohead grows away from the membrane by simultaneous addition of capsid and core proteins (or in an alternative view, by addition of capsid proteins gp23 and gp24 around a preformed core) until assembly is halted by the formation of the distal cap when the correct length is reached. Assembly is also dependent on the host GroEL chaperone and the phage co-chaperonin T4 gp31 because their action is required for correct folding of the major capsid protein gp23. DNA packaging (see earlier) is accompanied by expansion of the prohead from its initial rounded shape into the angular prolate icosahedron form of the mature capsid. The DNA-filled head is completed by addition of specific proteins to the portal vertex and to the capsid surface. Proteins gp2 and gp4 are apparently added at the portal vertex, followed by neck proteins gp13 and gp14. T4 gp2 is thought to bind to the genome termini and protect the DNA from degradation by the host RecBCD nuclease after injection. Two *decoration proteins*, Hoc and Soc (155 and 870 copies, respectively), are also added to the outside of the shell. Hoc is located at the center of each hexameric gp23 capsomer, and six copies of Soc surround each capsomer, except for the vertices containing gp24. Both Hoc and Soc are dispensable, although Soc does confer additional stability to the capsid. Attached to the neck are also six trimeric whiskers of the Wac protein (also called fibrin), formed by extended coiled-coil structures.

A small set of T4 internal proteins (internal protein I [IPI], IPII, IPIII, and Alt) are specifically localized to the inside of the capsid where they are proteolytically cleaved at specific peptide bonds and subsequently injected into the host along with the DNA. These proteins contain a capsid targeting sequence that can be fused to other proteins such as GFP so as to target their introduction into the capsid.¹³⁰ The functions of some internal proteins are known; for example, IPI* protects the incoming DNA from an *E. coli* nuclease that is capable of digesting glucosylated hmC DNA (not all *E. coli* strains contain this activity, however).

Structure and assembly of the T4 tail is substantially complex, not only because of the larger number of protein components, but also because of the dynamic nature of the contractile tail¹⁰⁶ (Fig. 75.7). As with the capsid, a combination of cryo-

EM (Fig. 75.8) and crystallography have proven extremely informative in recent years, building on a wealth of genetic and biochemical experiments. The tail is composed of the baseplate, a tail sheath surrounding a tail tube, and long tail fibers; altogether it contains about 430 individual polypeptides, and tail assembly requires a total of 22 genes.

Assembly begins with the baseplate wedge, which is composed of seven different polypeptides (Fig. 75.8). The hub is independently assembled from gp5, gp27, and gp29 (the tail tape measure protein), which then joins with gp12, gp9, gp48, gp54, and six preassembled wedge components to form the baseplate, along with its short tail fibers (gp12). The tail tube (composed of 138 copies of gp19) assembles onto the baseplate, gp18 forms the tail sheath around the tube, and gp3 and gp15 cap the top of the tail. The long tail fibers are bent rods composed of trimers of gp34, gp36, and gp37 and a hinge composed of gp35. They are made by a separate pathway from the rest of the tail with the aid of gp38 and gp57A chaperones. Tail fibers normally attach to the baseplate only after heads and tails are joined and attach to the gp9 socket protein on the baseplate. Both the Wac whiskers and gp63, a protein that is also an RNA ligase, have been found to accelerate tail fiber addition. As a general rule, the assembly of the individual components of tails and tail fibers follows a strict order (with a few exceptions), such that omission of one component or protein halts assembly at the stage when that component is required.

Adsorption of T4 to *E. coli* involves recognition of the outer membrane-located OmpC receptor by the long tail fibers, specifically the C-terminal tip of gp37. This association results in a large conformational change in which the hexagonal-shaped baseplate opens up into a star shape, the sheath contracts, and the internal tube is pushed through the baseplate and through the cell envelope, with the lysozyme action of gp5 facilitating passage through the peptidoglycan layer. The tape measure protein gp29 is presumed to exit the tube so that DNA can be released from the capsid, through the tube, and into the cytoplasm of the cell. In this process, the baseplate and sheath essentially adopt two alternative configurations: a hexagonal baseplate with an extended sheath, and a “star” baseplate configuration with a contracted sheath. The transition from one to the other involves numerous dynamic changes, with perhaps the most prominent being the rotation of more than 100 degrees of the gp10–gp11 complex that attaches the side tail fibers to the baseplate. As a consequence, the short tail fibers unfold from under the baseplate and extend toward the cell surface. A movie of a reconstruction of the whole T4 injection process is available at <http://www.youtube.com/watch?v=41aqxcxsX2w>.

Antigen Display

Because Hoc and Soc are dispensable for the formation of mature virions, they provide an intriguing platform for display of antigens and other proteins on the outside of the head shell. Fusion proteins containing the gp23 association sequences of Hoc or Soc attached to an antigen of choice can be expressed during infection of a Hoc- and Soc-defective mutant of T4 to generate decorated particles. Alternatively, purified fusion proteins can be assembled onto *hoc*[−] *soc*[−] mature virions *in vitro*. The ability to add a large number of epitopes—up to 1,895—onto a single virion is a particularly attractive feature.¹¹⁰ These approaches have been successfully demonstrated for antigens

FIGURE 75.7. Assembly of the T4 tail. Assembly of the wedge (**A**), the baseplate (**B**), and the tail tube (**C**) with the sheath. (From Leiman PG, Arisaka F, van Raaij MJ, et al. Morphogenesis of the T4 tail and tail fibers. *Virology* 2010;7:355.)

of a variety of pathogens including human immunodeficiency virus (HIV), poliovirus, swine fever virus, foot-and-mouth virus, and *Neisseria meningitidis*.^{151,165} Some of these show considerable promise as vaccine candidates, including for protection against anthrax.¹³⁶

This approach for virion decoration has also been applied to the construction of small peptide libraries and using these to identify associating proteins. In one example, libraries of the T4 large terminase subunit were panned and a peptide identified that interacts with the late sigma factor, gp55, and subsequent analysis showed that gp55 plays a role in loading the terminase onto the viral genome.¹¹⁴

OTHER TAILED PHAGES

The *E. coli* phages T4 and λ are the most extensively studied individual phages of the $\sim 10^{31}$ on the planet, and they have shown the way over the past approximately seven decades to a

remarkable number of fundamental insights into how viruses earn their livings and interact with their hosts, not to mention revealing some of the most basic aspects of molecular biology. However, another lesson from studies of tailed phages is that they are astonishingly diverse, both in their genetic content and in the genetic and biochemical mechanisms they have developed. Here we present a small selection of other well-studied tailed phages, emphasizing only features of their life cycles that are not found in λ or T4.

Bacteriophage HK97

E. coli phage HK97 was a relatively unknown distant relative of phage λ , but it was selected for further study because it morphologically resembled λ but has a longer tail.⁷⁹ However, HK97 has become an important model system for capsid assembly and structure because of a relatively simple capsid assembly pathway that is experimentally amenable (Fig. 75.9A). HK97 requires only three proteins to direct capsid assembly of its T = 7 capsid: the portal protein, the protease, and the major capsid

FIGURE 75.8. Cryoelectron microscopy (cryo-EM)-derived model of the T4 phage particle prior to **(A)** and upon **(B)** host cell attachment. Tail fibers are disordered in the cryo-EM structures, as they represent the average of many particles each having the fibers in slightly different conformations.

protein. Missing from this list is the scaffolding protein identified as a required assembly factor in all tailed phages studied previously. In HK97, the scaffolding protein role is played by an ~100 residue N-terminal extension of the major capsid protein called the delta domain. Like the scaffolding proteins of other phages, the delta domain is removed after assembly by the HK97 capsid maturation protease, and the digested pieces exit from the particle. This proteolysis makes the assembly essentially irreversible and results in a particle (prohead II) that is ready for DNA packaging; subsequent conformational changes lead to the expansion of the particle from the round prohead shape to the larger angular shape of the mature form, head II.⁴³

A particularly surprising aspect of HK97 virion assembly is how the mature capsid protein is stabilized, using covalent cross-links between the major capsid subunits.¹⁹¹ This is in contrast to phages that use *decoration proteins*, such as λ and T4 (as described earlier), or phages such as P22 and T7, which achieve their stable mature forms by conformational changes alone. The covalent bonds in HK97 act like rivets between the inside and outside of the capsid, forming between a lysine—part of a secondary structure element on the outside of the capsid, the “E-loop”—and an asparagine on an inner part of a separate subunit. The reaction occurs during the conformational changes of maturation, which brings the two cross-link residues into a reaction center containing a third residue, glutamic acid, which is required to “catalyze” the reaction

(Fig. 75.9C). There are 415 of these cross-links, which also change the overall topology of the capsid polypeptide chains into covalent circles that are interlocked in a way that resembles chain mail.¹⁹¹ This results in an unusually stable capsid.

All of the capsid assembly intermediates illustrated in Figure 75.9 have had their structures determined by cryo-EM, so there is a wealth of information about the conformation changes that occur, at increasingly higher resolutions as techniques improve.^{43,103} The very stable cross-linked HK97 mature capsid was the first of the tailed phage capsids to yield a structure by x-ray crystallography¹⁹¹ (other HK97 intermediates have also yielded x-ray structures since). The fold of the subunits found in the HK97 capsid (Fig. 75.9C), dubbed the HK97 fold because it was unique among known tertiary structures at the time, has since been found in virtually all other tailed phage capsid proteins that have been studied so far, and also in the inner part of herpesvirus nucleocapsids. The x-ray models of HK97 combined with lower-resolution cryo-EM density maps have enabled a fairly complete description of the later stages of HK97 maturation,^{79,103} and it is hoped that similar work on the earliest stages (Fig. 75.9B) will help complete the story and shed light on the mechanism of capsid size determination, which is still poorly understood.

Bacteriophage T7

E. coli phage T7 is one of the seven classical “type” virulent phages anointed by Max Delbrück as appropriate for study in the early days of phage molecular biology.¹²⁶ T7 is a strictly lytic phage with a short (~20-minute) life cycle; if T4 is the *Tyrannosaurus rex* of phages, T7 is the *Velocinaptor*. The genomic DNA in the T7 virion is not permuted, and all the genes are transcribed in the same direction. Upon infection, only the first 7 kbp of the “left” end of the DNA, corresponding to the upstream end of transcription, enter the cell initially. This segment of DNA contains three strong, tandem promoters recognized by the host RNA polymerase, leading to transcription and expression of a small number of genes. These include a protein that inactivates restriction enzymes but, most importantly, includes the phage RNA polymerase. This is the highly efficient single-subunit RNA polymerase that has been used to drive expression in many plasmid protein expression vectors. For T7, its job is to transcribe the remainder of the phage genes, starting from a phage-specific promoter near the end of the short sequence of DNA that was initially injected into the cell. Remarkably, entry of the remaining 83% of the genomic DNA into the cell is driven by transcription by the phage RNA polymerase; as the polymerase transcribes in the direction of the DNA still in the phage capsid, its translocation along the template pulls the remainder of the DNA into the cell.¹²⁷

In light of T7’s long-standing reputation as a quintessentially lytic phage, it was a surprise when a T7-like prophage (!) was found in the genome of a *Pseudomonas putida* strain.³⁰ The prophage has an essentially complete inventory and arrangement of T7 family genes, with an extra ~4 kbp of DNA at the right end of the genome encoding an integrase and at least three additional proteins of unknown function. Unlike in the better-studied prophages, the gene order of the T7-like prophage is not circularly permuted relative to the gene order in the virion DNA. Like many other prophages, the T7-like prophage is integrated into the middle of a tRNA gene and appears to have restored an intact tRNA gene with a copy of

FIGURE 75.9. Assembly of HK97. **A:** PI is prohead I, the first intermediate, and PII is prohead II, which is the cleaved form after proteolysis. EI-I, EI-II, EI-III, and EI-IV are expansion intermediates, as detected in.¹⁰³ HIII is the mature HK97 capsid containing fully cross-linked major capsid protein. Numbers in parentheses on the left are copy numbers of proteins used. **B:** Cryoelectron microscopy reconstruction of HK97 prohead I with three hexons labeled with a 6 and three pentons labeled with a 5. (J. Conway, A. Steven, N. Cheng, R. Duda, and R. Hendrix, unpublished data.) **C:** Subunit F extracted from the head II structure (PDB ID 1OHG) showing major elements of the structure and the three residues involved in cross-link formation.

the downstream half of the tRNA gene encoded at one end of the prophage.

Bacteriophage P22

The genetic diversity of the lambdoid phages is legendary among virologists, and nowhere is this more clearly demonstrated than in their head assembly genes. There are currently nine types of lambdoid phages known whose head genes have diverged to the point where their major capsid protein amino acid sequences are not recognizably similar, and there are significant parallel variations in their head assembly mechanisms.³³ One of these nine types is exemplified by *Salmonella enterica* phage P22, a temperate phage with a 41,724-bp genome.¹³⁸ Its genes are organized and regulated like those of λ , but its virion has a very short tail (it is a member of the *Podoviridae* family; Table 75.1), and unlike λ it utilizes a headful packaging strategy. P22 was discovered at about the same time as λ , but it was immediately noticed that, unlike λ , P22 could transfer host genetic material from one *Salmonella* cell to another.²⁰⁰ This process was called *generalized transduction* because any host gene could be transferred in this way. It is now known that the P22 DNA packaging apparatus occasionally makes a mistake

and initiates packaging on the host chromosome instead of on its own phage DNA.¹¹⁸ P22 is a headful packaging phage, and the headful nuclease that cuts the packaged DNA from the long packaging substrate DNA has little sequence specificity. So, when a head is full of host DNA, the headful nuclease cuts the packaged DNA from the host chromosome, normal tails assemble on these heads, and a “virion” is produced, which is in all respects identical to a genuine P22 virion except that it contains a single ~43-kbp molecule of host DNA instead of the phage chromosome. Such a “transducing virion” can, like an authentic P22 virion, inject its host DNA payload into a susceptible *Salmonella* cell, but this DNA cannot replicate and does not encode P22 proteins. This would be a dead end of no consequence, except that the injected host DNA can replace the parallel portion of the new host’s chromosome by homologous recombination that is mediated by host cell proteins.¹¹⁸ Because P22 does not inject any toxic proteins with its DNA, this recipient cell can survive the experience, and if there are genetic differences between the original donor host and the new recipient host, these differences can be transferred from the donor cell to the recipient cell by this transduction process. Geneticists studying *Salmonella* soon found this to be an

extremely useful way of moving specific genetic alleles from one *Salmonella* strain to another, and small terminase subunit mutants of P22 were found that had error-prone DNA packaging machinery that made the process much more efficient.³¹ Soon generalized transducing phages had been isolated to perform this function for many bacterial species. For wild-type generalized transducing phages, virions with host DNA typically make up 0.1% to 2.0% of the total virions made during an infection, but the frequency of transduction of any given allele from one host to another is considerably lower than this, because only a small fraction (1% to 3%) of the transducing virions carry host DNA that contains any particular host DNA sequence. In addition, the efficiency of recombination of the injected host DNA with its resident homolog is much less than 100%.¹¹⁸ Nonetheless, successful transduction frequencies as low as one in a million recipient cells can be utilized in the laboratory, and transduction remains a common tool of bacterial genetics. Generalized transduction certainly also occurs in nature, where it is thought to be responsible for much of the genetic exchange that happens between bacteria in the wild.

P22 was also the first phage found to encode an *antirepressor* or protein that antagonizes its prophage repressor.¹⁷⁵ P22 antirepressor protein binds the P22 prophage repressor and stops it from binding to its operator. In this way the presence of antirepressor can initiate prophage induction or prevent establishment of lysogeny. Expression of the antirepressor gene is controlled by two other P22 transcriptional repressor genes (*mnt* and *arc*) and a small RNA gene (*sar*).¹¹¹ The Mnt repressor binds its operator, which overlaps the antirepressor gene's promoter, and keeps transcription from initiating there in the prophage state. However, if the Mnt repressor releases its operator, antirepressor protein is made, and it in turn inactivates the prophage repressor so that prophage induction ensues. The small *sar* RNA, which blocks translation of antirepressor mRNA, and both Mnt and Arc transcriptional repressors are all required to lower antirepressor synthesis to the very low level required for P22 to establish and maintain the lysogenic state. The *sar* RNA was one of the first untranslated regulatory RNAs to be discovered and characterized.¹¹¹ Antirepressors of several types are now known to be fairly commonly encoded by temperate phage genomes.

Some tailed phage virions utilize polysaccharide receptors to adsorb to the bacterial surface. P22 is such a phage, and it was instrumental in the discovery that such virion receptor-binding proteins (tailspikes) are usually also enzymes that cleave these surface polymers. P22 virions have 6 trimeric tailspikes and so have 18 polysaccharide binding/cleavage sites. The detailed role of this cleavage is not completely understood, but it appears to allow the virion to work its way down to the outer membrane surface.³⁵ Such tailspikes are very specific for the particular sugars that make up the polysaccharide chain, which means that these phages are very specific for particular bacterial subspecies, strains, or "serovars." P22, for example, only adsorbs to a small fraction of *Salmonella* cells, those whose O-antigen polysaccharides are built with a mannose-rhamnose-galactose repeat. This specificity of P22 tailspike binding can be used to identify its host bacterium, *S. enterica* serovar Typhimurium.¹⁷⁷ Phages that infect *Enterobacteriaceae* bacteria (the family that includes *Escherichia*, *Shigella*, *Salmonella*, *Serratia*, etc.) are known that carry similar tailspikes with at least 51 different polysaccharide specificities.³⁶ All these phages are most likely similarly

restricted to infecting a small subset of their host species, and the surface polysaccharide of their hosts could presumably be identified in a similar manner. Some phage virions carry more than one tailspike, and they can adsorb to and infect multiple hosts that have surface polysaccharides to which their different tailspikes bind.¹⁶⁷

The genetic diversity and mosaicism of the phage P22 virion assembly genes have been particularly well studied. These phages have been evolving for a very long time, and even in a phage group as narrowly defined as the P22-like lambdoid subgroup, the coat proteins have diverged *within* this group to the point that some pairs are less than 15% identical in amino acid sequence, apparently without genetic contact with coat genes from other tailed phage types.¹³⁵ Other proteins involved in recognition of DNA to be packaged and in receptor binding are even more variable (see earlier), and in these two cases there has been horizontal acquisition of some gene types from other more distantly related tailed phage groups.³⁶ In addition, there has been extensive genetic exchange among the various phages *within* the P22-like group, and in many cases parts of genes that encode protein domains rather than whole genes have been exchanged.

Bacteriophages P2 and P4

Bacteriophage P2 is the best-characterized member of a large family of temperate *Myoviridae* found in the genomes of γ -*Proteobacteria*.¹³² It was isolated in 1951 by Bertani¹⁶ from the oldest known lysogen, the Lisbonne and Carrère strain of *E. coli*, along with phages P1 and P3. One hallmark of P2-related phages is their lack of ultraviolet (UV) inducibility; unlike the lambdoid phages, repressors of P2-related phages are not cleaved in the presence of activated RecA.

P2 is among the smallest *Myoviridae*, with a genome of 33,593 bp; the virion DNA is linear and double stranded, with 19-bp cohesive ends. DNA replication proceeds by a modified rolling circle mechanism reminiscent of that used by single-stranded DNA phages such as ϕ X174, and like ϕ X174, P2 depends on the host *rep* helicase.¹³² Replication requires a *cis*-acting phage-encoded initiator protein, the A protein, that catalyzes cleavage at the origin and becomes covalently linked to the 5' end of the cleaved strand. It acts again at the end of replication to cleave the newly synthesized origin and rejoin the displaced old strand. The resulting products are monomeric double-stranded circles, an unusual substrate for packaging of double-stranded phage DNA but one that is required for the P2 packaging reaction.¹⁸

All P2 transcription is carried out by the host RNA polymerase. As in other temperate phages, early transcription initiates from a pair of divergent promoters encoding the lysogeny and replication functions. The P2 immunity repressor, C, differs from the majority of phage repressors in that it recognizes nonpalindromic direct repeats of DNA, even though it is structurally similar to repressors that bind to inverted repeats. P2 C regulates its own promoter and blocks expression of the rightward operon encoding the replication genes and *cox*, which encodes the repressor of the lysogenic promoter. P2 Cox is unusual in that it functions not only as the repressor of the lysogenic promoter but also as the recombination directionality factor for prophage excision.¹⁹⁹

Transcription of the P2 late genes requires the product of the phage *ogr* gene, a transcriptional activator that binds to a

conserved sequence about 55 bp upstream of the initiation sites for the four P2 late promoters.³⁹ Ogr was the earliest example of a transcription factor that interacts with the α subunit(s) of *E. coli* RNA polymerase. It is a small zinc-binding protein found almost exclusively among P2-related phages and their satellites, with a Cys₂Cys₂ motif essential for metal binding and activity.

Capsid assembly has been studied extensively in P2, largely in the context of its relationship as a helper phage for satellite phage P4, which is discussed in more detail later. P2 has also served as a model for bacteriophages with contractile tails. An exciting recent development was the demonstration that the bacterial membrane-penetrating protein, gpV, is an iron-binding spike.²⁰

P4 was discovered in the early 1960s by Erich Six and was initially characterized as a satellite bacteriophage dependent upon a P2 helper phage for lytic growth. Subsequent work has shown that P4 may be more appropriately considered to be an integrative plasmid that acquired the ability to exploit a helper phage for highly specialized horizontal transfer.¹³² In the absence of a helper genome, P4 can be maintained as an integrated prophage or as a multicopy plasmid. P4 replicates its DNA by θ mode in both the multicopy plasmid state and during the lytic cycle, and this replication is independent of helper phage functions. P4 immunity is regulated by a novel mechanism involving transcription termination caused by sequence-specific binding of a short stable immunity RNA. This immunity RNA is processed out of the same transcript that it regulates.

Exploitation of P2 by P4 can occur in several situations, including P4 infection of a P2 lysogen, P2 infection of a strain carrying P4 in either the immune-integrated or multicopy plasmid state, and co-infection by both phages. In each of these cases, P4 responds to the presence of the helper phage by activating functions that allow it to modify P2 gene expression appropriately. The nature and timing of the regulatory cross-talk depends on the infection conditions and appears to be designed to optimize P4 reproduction. One set of reciprocal regulatory interactions between P4 and P2 allows mutual derepression. The P4 Epsilon protein binds to the P2 immunity repressor and interferes directly with its function. Derepression of P4 by P2 requires a third activity of the P2 Cox protein, which stimulates transcription of the operon encoding the P4 replication functions from a promoter that bypasses the P4 immunity system. A second set of reciprocal interactions regulates late gene transcription. The two P4 late promoters are activated by P2 Ogr, the same protein required for P2 late transcription. One of the P4 late gene products, Delta, is an Ogr homolog that activates the same two P4 late promoters and the four P2 late promoters.⁸⁹ This mutual transactivation allows earlier expression of P4 late genes in the presence of a P2 helper. It also allows P4 to activate directly the transcription of the P2 morphogenetic genes required for packaging and lysis, bypassing their normal requirement for P2 replication.

The P4 lytic cycle requires all of the morphogenetic functions of the helper phage. A striking feature of the P2–P4 interaction is the redirection of the viral capsid assembly pathway. The 33-kb P2 genome is packaged into icosahedral, isometric T = 7 capsids with a 60-nm diameter. Satellite phage P4 packages its smaller (11,624 bp) genome into a T = 4 particle formed by the interaction of the P4-encoded size determina-

tion protein, Sid, with the P2 major capsid protein, gpN. The P2 scaffolding protein, gpO, is an internal scaffold required for assembly of the larger T = 7 P2 procapsids. Both P2 and P4 require gpO for capsid maturation; in addition to its role as a scaffold, it also acts as a protease for N-terminal processing of both gpN and itself. P4 Sid functions as an external scaffold, forming a size-restricting cage that influences the bending of the phage capsid protein at a flexible hinge region. Mature P4 virions have lost the external Sid scaffold but contain a P4-encoded decoration protein, Psu, that helps to stabilize the smaller capsid. The smaller P4-induced capsid cannot accommodate the P2 genome, leading to interference with helper phage growth.¹³²

Bacteriophage G

Bacillus megaterium phage G is the largest phage known and among the nonphage viruses is exceeded in size only by the Mimiviruses. The G genome is 497,513 bp long, with nearly 700 predicted protein genes and 17 tRNA genes.⁷⁵ Fewer than one-third of the predicted protein sequences match any sequences in the databases. The sequences with good database matches include some virion structural proteins, DNA replication functions, and a wide variety of metabolic enzymes. Compared to phages with smaller genomes, phage G has an unusually large number of apparent transcription factors and even has some translation components, including the tRNAs and an apparent tRNA synthetase, features that have also been reported for the very large eukaryotic Mimiviruses.

Bacteriophage Mu

E. coli phage Mu (*Mu* is short for “Mutator” and is not the Greek letter) is a temperate phage that gets its name from the fact that the prophage integrates at essentially random positions around the host chromosome, often inactivating genes into which it inserts.¹³⁴ Mu is a transposon as well as a bacteriophage, and when it grows lytically it replicates its DNA by replicative transposition, resulting in ~200 copies of the phage genome inserted around the host chromosome. These phage genomes are excised from the host DNA and packaged into procapsids in such a way that some flanking host DNA is included in the DNA in the virion— 50 to 150 bp on the left end and 1 to 2 kbp on the right end. In this sense the Mu genome is always inserted between flanking host sequences, whether it be in the virion particle, as a prophage, or replicating lytically.

Another striking and unusual feature of Mu, shared with only a minority of the extensive family of Mu-like phages, as well as with some members of the P1-like and P2-like phage families, that have been described is that it has two alternative types of tail fibers, which give it two alternative host ranges. It achieves this by having a 3-kb invertible segment of DNA (the “G segment”) containing sequences that encode two alternative C-terminal halves of the tail fiber, one on each end of the G segment.²² The orientation of the G segment in the genome determines which of these alternative C-terminal half-genes is fused to the half-gene located immediately adjacent to the upstream side of the G segment encoding the N-terminal half of the tail fiber. The N-terminal half of the tail fiber attaches the fiber to the phage tail and the C-terminal half contains the host cell receptor binding specificity, determining the host range. Inversion of the G segment is mediated by a DNA invertase,

Gin, encoded within the G segment. Gin is a member of a family of invertases, including the Hin invertase of *Salmonella*, which is responsible for flagellar antigen switching.

Bacteriophages P1 and N15

Just as phage Mu is both a bacteriophage and a transposon, *E. coli* phages P1 and N15 are both bacteriophages and plasmids. N15 is a temperate phage with a 46,363-bp genome that has many features in common with phage λ . P1 is a different type of temperate phage whose genome is considerably larger (93,601 bp). In the lysogenic state these two phages do not integrate their DNA into the host chromosome. The P1 and N15 prophages replicate as linear and circular plasmids, respectively.^{150,197} P1 is a generalized transducing phage and a classical tool of *E. coli* genetics,¹¹⁸ and it also played a critical early role in the discovery of restriction endonucleases (the P1 genome encodes such an enzyme), which in turn was critical in the early development of genetic engineering.⁴¹

The P1 and N15 prophage plasmids are both present in low copy number close to the number of bacterial chromosomes in the cell, and the study of P1 was important in our current understanding of how bacterial plasmids are partitioned into the two daughter cells during cell division.⁵⁷ Both phages encode two proteins, ParA and ParB, that are responsible for accurate plasmid segregation. ParB molecules bind to a centromere-like site(s) on the phage DNA to form a large macromolecular structure, and ParA protein is an ATPase that can form filaments and binds to ParB. The precise mechanism of control of plasmid partitioning by these proteins is not yet known, but it has been speculated that polymerization of ParA into filaments acts to push or pull the plasmid DNAs into the daughter cells.⁵⁷ In spite of the fact that P1 does not integrate its prophage into the host chromosome, it encodes a site-specific DNA recombinase, Cre protein, that performs several roles for P1, including aiding prophage plasmid segregation by resolving dimer circles (that form by homologous recombination between two monomers) into two monomer circles.¹⁹⁷ The Cre/*lox* recombination system has been applied to the genetic engineering of higher organisms with great success, where it is used to cause gene targeting or deletion to occur in response to a specific environmental signal or to occur only in a specific tissue.¹⁶⁶

Most bacterial DNAs are circular, so the fact that the N15 prophage plasmid is a linear dsDNA molecule is unusual. At the ends of this plasmid the two strands are joined covalently to form a closed hairpin at each end. The mechanism by which the N15 plasmid prophage is formed is interestingly analogous to the mechanism of λ prophage integration. The DNA in the N15 virion, like λ virion DNA, is linear dsDNA with 12 base ssDNA cohesive ends that join upon DNA injection to circularize the molecule. When the phage enters the lysogenic cycle, this circular form of the DNA is converted into the linear prophage form by integrase in the case of λ and by a phage-encoded enzyme known as protelomerase (“prokaryotic telomerase”) in the case of N15.¹⁴⁹ Protelomerase binds to a *tel* site adjacent to its gene, analogous to λ 's *attP*, and cuts both strands of the DNA. But instead of joining the cut ends to host DNA, it joins the 5' end of each strand to the 3' end of its complementary strand, thus forming the hairpin ends of the linear prophage plasmid.⁸⁵ Replication of the linear N15 plasmid then proceeds as normal semiconservative duplication by separation

of the two parental strands and synthesis of the complementary strand without breaking the parental DNA chain. This converts the linear molecule into a dsDNA head-to-head dimer circle, which is in turn resolved into two hairpin-ended linear molecules by action of the protelomerase at the two *tel* sites in the dimer circle.¹⁴⁹

Bacteriophage ϕ 29

The *Bacillus subtilis* bacteriophage ϕ 29 is a small, dsDNA lytic virus of the *Podoviridae* family. Although λ and T4 were being investigated intensively in the mid-1960s, ϕ 29 was chosen for study because it is small (~20 genes) yet shares some of the complexities of other larger phages, including a prolate (elongated) head and a complex, noncontractile tail.⁴ From the start, the study of ϕ 29 held the promise of understanding the function of every gene and of isolating and characterizing every intermediate of the assembly pathway. The system was deemed well suited to investigate complex questions such as the mechanism of form determination, the regulation of assembly *via* sequential protein and DNA conformational changes, and the mechanism of DNA packaging. ϕ 29 has since proven to be a rich model system, especially for the study of DNA replication and the DNA packaging phase of viral assembly.

The genome of ϕ 29 is a linear, unit-length (i.e., nonconcatemeric) chromosome of ~19.3 kbp.^{121,161} The ϕ 29 chromosome is unusual in that a phage terminal protein, gp3, is covalently bound to each 5' end of the DNA via a phosphoester bond. Terminal proteins are also found in the chromosomes of some other phages, such as PRD1 and the eukaryotic adenoviruses. These proteins are essential for DNA replication, which proceeds by a protein-primed mechanism. In ϕ 29, a specific serine residue of gp3 provides the free 3'-OH needed to initiate DNA replication. Replication is bidirectional, with the viral-encoded polymerase, gp2, forming a complex with a free gp3 at both ends of the DNA and then catalyzing covalent attachment of a 3'-deoxy-adenosine monophosphate (dAMP) to the terminal protein. The complex “slides back” to the first nucleotide, and DNA synthesis proceeds from this single priming event. This mechanism allows ϕ 29 to overcome the challenge of replicating the ends of linear DNA without loss of genetic information. The monomeric phage-encoded DNA polymerase is notable in that it has been shown to have exceptionally high processivity, and it is capable of both polymerization and template-strand displacement, precluding the need for a helicase to unwind the template DNA.

During dsDNA phage virion assembly, the genomic DNA is packaged into a preformed protein shell (prohead or procapsid).¹⁴⁷ This process is driven by an ATP-dependent molecular motor that transiently assembles at the unique portal vertex of the head. In most phages, the motor consists of the connector and a terminase complex composed of large and small subunits that house the ATPase/nuclease and DNA recognition functions, respectively. In ϕ 29, the covalently bound terminal proteins are also essential for packaging,¹²⁸ likely providing the role of the small terminase subunit. The ϕ 29 packaging ATPase is smaller (~60%) than other phage large terminase subunits, in part due to the lack of a required nuclease function as the packaging substrate is already unit length. Additionally, ϕ 29 is unique in that a small noncoding RNA is also an essential component of the motor. This 174 nucleotide prohead RNA (termed pRNA) forms a novel pentameric ring via intermolecular base

FIGURE 75.10. Packaging of $\phi 29$ DNA. The $\phi 29$ DNA packaging motor. **A:** Cutaway view of cryoelectron microscopy reconstruction of the prohead/motor complex showing the molecular envelopes of the motor components.¹²⁸ Gray is the capsid, green is the head–tail connector, magenta is the prohead RNA (pRNA) ring, and blue is the packaging ring adenosine triphosphatase (ATPase) gp16. A DNA model has been placed in the channel for reference. (**A** from Grimes S, Ma S, Gao J, et al. Role of phi29 connector channel loops in late-stage DNA packaging. *J Mol Biol* 2011;410:50–59, copyright 2011, with permission from Elsevier.) **B:** Close-up of the motor components. pairing.¹²⁸ The pRNA ring serves to bridge the connector and the ATPase rings in the packaging motor.^{55,68} Because all the dsDNA phages are thought to employ similar packaging mechanisms, the functions of pRNA likely reside in subdomains of the larger motor proteins of other phages¹⁴⁷ (Fig. 75.10). Movement of DNA into the head is driven by the ATPase gp16. Like the analogous large terminase enzymes of other dsDNA phages, this ATPase ring is related to a large class of cellular ring ATPases that perform many substrate translocating functions.²³

A ring motor can work using a mechanism where each subunit works independently, or alternatively, two or more motor subunits can work together via a more complex and coordinated mechanism. Single-molecule laser-tweezers studies indicate that DNA translocation subunits are coordinated such that the ring loads with ATP while holding the DNA during a “dwell” phase, then hydrolyzes these ATPs to drive a “burst” of 10 base pairs into the head that is coupled to the release of inorganic phosphate from the motor. This high degree of coordination requires communication between motor components, possibly mediated through adjacent ATPase subunits, the pRNA ring to which it is bound, and/or the DNA substrate itself.

Studies of $\phi 29$ and other phage motors have revealed that the packaging motor is powerful when compared to other biological molecular motors, generating forces over 65 piconewtons, which is approximately an order of magnitude stronger than skeletal myosin.^{147,168} In part this high-force-generating capacity is required to overcome the resistance encountered when compacting the highly charged and relatively stiff DNA to near-crystalline density inside the head.

INSIGHTS FROM OTHER PHAGE FAMILIES

Tectiviridae: dsDNA, Linear, with Proteins on 5' Ends

Tectiviruses, typified by *E. coli* phage PRD1, share with the tailed phages (*Caudovirales*) a linear dsDNA genome in the virion as well as a few general features of their infection strategy, but in many ways they are quite distinct. Perhaps the most prominent difference is that the tailless PRD1 virion contains a lipid membrane, located inside an icosahedral protein capsid and surrounding the viral DNA⁶⁷ (Fig. 75.11). Its linear DNA is 14,927 bp long, not permuted, with inverted terminal repeats at the ends. Thirty-seven genes have been identified that are arranged in five operons. Promoters for the two early operons are in the terminal repeats, pointing toward the middle of the DNA, and the three late transcripts fill the center of the map, all oriented in the same direction.⁶⁷ The 5' ends of the two DNA strands are covalently joined to a phage-coded protein that serves as the primer for DNA replication by a phage-coded polymerase.

The high resolution x-ray structure available of the entire virion reveals several noteworthy features of PRD1 structure.¹ The major capsid protein, also known as P3 or hexon protein, has two β -barrel domains, each structurally similar to the single β -barrel domains that are found in many virus capsids. P3 trimerizes into a “hexon” that has a nearly sixfold symmetric arrangement of β -barrel domains and occupies the position in the capsid lattice that would be occupied by a hexamer in a canonical Caspar-Klug icosahedral structure. A different protein occupies the icosahedral vertices as a pentamer. These

FIGURE 75.11. Architecture and structural components of bacteriophage PRD1. PRD1 is composed of four protein subunits P3, P16, P30, and P31, surrounding a membrane. P30 is a linearly extended protein that nucleates the formation of the icosahedral facets (composed of trimers of the major capsid protein, P3) and acts as a molecular tape measure, defining the size of the virus and cementing the facets together. Pentamers of P31 form the vertex base, interlocking with subunits of P3 and interacting with the membrane protein P16. **A:** Strands of the second of two jelly-roll domains in the PRD1 capsid subunit, P3. **B:** The building blocks of a facet (the triangular area defined by white lines). The icosahedral asymmetric unit contains 12 P3 subunits arranged as four trimers, with orientations represented by triangles labeled 1 to 4 and colored yellow, green, blue, and cyan, respectively (the underlying gray hexagons show the trimer morphology; numbers and symbols follow the adenovirus convention). P3 trimers outside the marked facet are colored similarly and shown as coil, as is protein P31, drawn in red. **C:** Stereo C α traces of the superposed 12 unique copies of major capsid subunit P3, showing switching at the N (blue and cyan) and C (red and magenta) termini. **D:** Protein P30 is shown on the left in royal blue, with the SeMet differences in magenta. Part of a twofold related P30 subunit is shown in yellow. Dimensions are in angstroms. On the right, 60 copies of P30 (colored blue through green to red from the N-terminus to the C-terminus) wrap around the electron density of the membrane. The small holes in the membrane close to the fivefold axes are the transmembrane helices of protein P16. **E:** Stereo view of P31. Jelly-roll strands are labeled B to G; the β -strand at the N-terminus is labeled A. N-terminal and C-terminal segments are colored blue and red, respectively. (From Abrescia NG, Cockburn JJ, Grimes JM, et al. Insights into assembly from structural analysis of bacteriophage PRD1. *Nature* 2004;432:68–74, with permission.)

hexons and pentons are arranged in a pseudo $T = 25$ structure. There are two additional proteins forming the spike structure at the fivefold symmetry position but displaying symmetry mismatch. The spikes are involved in receptor recognition. One of the 12 vertices is a portal for the DNA packaging process where the DNA enters an empty procapsid through the protein and membrane layers of the virion.¹⁷¹ The virus release utilizes similar mechanisms to those operating in tailed bacterial viruses where a holin protein makes an opening to the plasma membrane and a lytic enzyme digests the peptidoglycan layer leading to cell disruption and virus release.

Microviridae: ssDNA, Circular

The *Microviridae* are small viruses with icosahedral capsids that contain the genome in the form of a circular ssDNA molecule. They are typified by the *E. coli* phage ϕ X174, genome size 5,386 nucleotides, with which most of the experimental work with this group has been done.⁶⁰ A few tens of rather close relatives of ϕ X174 have been isolated on enterobacterial hosts, and these have been used in comparative experimental studies with ϕ X174 as well as in evolution studies.¹⁹⁰ A second small group of isolates infects hosts of the *Chlamydia*, *Bdellovibrio*, and *Spiroplasma* genera of bacterial hosts. This group of viruses shares general features with the ϕ X174 group but differs

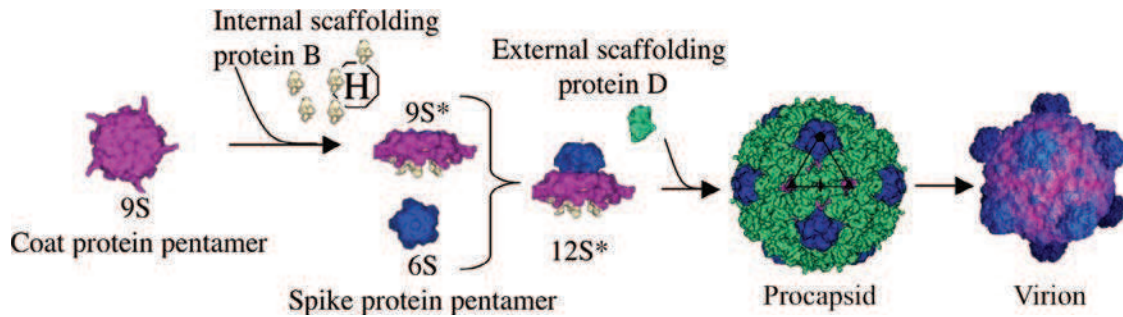

FIGURE 75.12. Assembly of ϕ X174 particles. The first identifiable assembly intermediates are pentamers of the viral coat F and major spike G proteins, the 9S and 6S particles, respectively, which can form in the absence of both scaffolding proteins. Five internal scaffolding B proteins bind to the underside of the 9S particle, yielding the 9S* intermediate. This interaction induces a conformational change that allows 9S*-6S particle associations, forming the 12S* intermediate. The internal scaffolding protein also facilitates the incorporation of the DNA pilot protein H. Two hundred and forty copies of the external scaffolding D proteins, most likely in the form of 60 tetramers, associate 12 12S* particles into the procapsid, a DNA-less particle. Both scaffolding proteins are removed from the procapsid when particles are filled with single-stranded DNA (ssDNA) during the last stages of the maturation.

in details of gene content and organization and of virion morphology; they are accordingly classified as a separate subfamily of the *Microviridae* family. Little has been known until recently about the abundance of the *Microviridae* in the environment. However, metagenomic studies of environmental samples have shown (when the sequencing technology employed can detect ssDNA) that *Microviridae* sequences are a significant component of the sequences in these samples that are recognizably of viral origin.¹⁷⁹

Infection by ϕ X174 begins with binding of the virion to the surface of the *E. coli* host, and electron micrographs of infecting virions show them at locations where the inner membrane and the cell wall of the host are closely apposed. The initial receptor on the host is a portion of the lipopolysaccharide, recognized by a glucose-binding site on the virion surface. Host range mutants of the phage map to a different part of the virion surface, suggesting that there is at least one more host receptor molecule. It is not known how the virion DNA crosses the cell envelope to enter the cytoplasm, but it appears that the virion proteins remain outside the cell.

The virion ssDNA is of the plus sense, so transcription to produce mRNA cannot start until replication of the DNA has produced the minus-strand template. In fact, the first stage of DNA replication, which converts the single-stranded circular virion DNA into a double-stranded circle, is carried out entirely by host replication proteins. The resulting double-stranded circle, called RF I (replicative form I), can serve as the template for transcription but also serves as the template for the second stage of replication, in which the dsDNA RF I circles are amplified to make more dsDNA circles, now called RF II.¹⁷² In addition to the host replication proteins required for converting virion DNA to RF I, this second stage of replication requires a phage-coded protein, the A protein, and an additional host protein, the *rep* helicase. The A protein binds to the replication origin, cuts the plus strand, and attaches the 5' end of the plus strand to itself by an ester bond. The *rep* helicase then unwinds the 5' end and replication proceeds by elongation of the free 3' end of the plus strand. This is the classical rolling circle form of DNA replication, first identified in

this phage. When the free single-stranded plus strand reaches unit length, the A protein cuts again and ligates the ends of the ssDNA to form an ssDNA circle. This ssDNA circle is identical to the virion DNA, and it is converted to the dsDNA circle, RF II, by the same host replication proteins that converted virion DNA to RF I.

The final stage of replication also uses a rolling circle mechanism initiated by the action of the phage-coded A protein, and the ssDNA plus-strand circles are produced as described for the second stage of replication. However, in this stage, replication takes place in a complex with the newly assembled procapsids. Formation of this complex is mediated by the phage-coded C protein. The ssDNA is apparently inserted into the procapsid as it is displaced from the rolling circle, with the packaging driven by the energy of replication (Fig. 75.12). Lysis involves a mechanism that alters the host *MraY* protein to interfere with cell wall synthesis.¹³

Inoviridae: ssDNA, Filamentous

Filamentous phages have striking morphologies, flexible long rods up to several micrometers in length, and diameters of only ~7 nm. These phages were first detected by Loeb¹¹² with phage f1, and later, M13 and fd were isolated, all of which are closely related and use *E. coli* as their host. Several other *Inoviridae* have been described with host bacteria other than *E. coli*,¹⁸⁷ but we will focus here on M13, perhaps the best studied of these phages.

M13 particles consist of a 6,407-base single-stranded DNA molecule that is helically coated by about 2,800 copies of a small (50 amino acids) major coat protein, gp8. The C-terminal sequence of gp8 is positively charged and interacts with the phosphate backbone of the DNA, stabilizing the phage particle. The tip of the phage has five copies each of gp7 and gp9, two minor coat proteins, whereas the base of the phage is made up of five copies each of gp3 and gp6 that are involved in adsorption to the host.

M13 adsorption to its host is quite distinct, is male specific, and uses *E. coli* F pili for attachment. The N2 domain of gp3 binds to the tip of the F pilus and induces a retraction signal in the pilus similar to that induced by a contact

with a female cell in bacterial conjugation. The F pilus retracts by sequential disassembly into the bacterial inner membrane²⁴ along with the phage that effectively extends the tip of the pilus. During this process the N1 domain of gp3 interacts with the periplasmic domain of the host TolA protein.¹¹³ As the coat proteins partition into the membrane bilayer upon pilus retraction, the single-stranded DNA is released into the cytoplasm where it is converted into double-stranded DNA by the host DNA polymerase.

Only 11 gene products are encoded by the M13 genome, most of which are involved in assembly of the virion. The major coat protein gp8 is synthesized as a “procoat” with a cleavable signal sequence and inserted into the inner membrane of *E. coli*. It is not a substrate of the signal recognition particle (SRP) and the Sec-translocase, but instead it requires the membrane insertase YidC for membrane localization.¹⁶² After insertion, the procoat protein is converted to mature coat protein by the leader peptidase of *E. coli*.¹⁰⁰ YidC is also involved in the membrane insertion of gp9.¹⁴² All the virion minor proteins, gp3, gp6, gp7, and gp9, are membrane proteins, as are gp1 and gp11.⁷⁰

Replication of M13 DNA proceeds by the rolling circle mechanism.⁸³ The endonuclease gp2 creates the free 5' ends that are required to form new single-stranded circles. These are first converted to dsDNA to increase the numbers of rolling circles, and later in infection, when the structural phage proteins are synthesized, the newly replicated ssDNA is covered by the phage-encoded ssDNA binding protein, gp5.

As early as 9 minutes postinfection, the first progeny are released from the host cells without lysis (Fig. 75.13). Virion assembly takes place at the host membrane, initiating with gp7 and gp9 to form the tip of the prospective virion. This likely

occurs within a transmembrane complex containing the membrane proteins gp1, gp11, and thioredoxin.¹⁴⁸ The ssDNA is then introduced into the assembly process by binding to the “packaging signal” in the M13 genome.¹⁶⁰ Oligomers of the major coat are then added to form a fivefold helical structure around the ssDNA that grows out from the cell surface.¹³¹ During this elongation process ssDNA moves through the membrane and is simultaneously covered by major coat protein subunits, replacing the bound gp5 molecules. Passage through the outer membrane is facilitated by a porin-like structure containing gp4.¹⁵⁹ Finally, the assembly process is terminated by attachment of gp3 and gp6 to the end of the phage. Thus, the length of the virion filament is determined by the length of the ssDNA genome.

The rate of phage production is constant with about six particles released per cell per minute,¹⁴¹ but because the particles are secreted, no host lysis occurs, and cell division continues, albeit at a reduced rate. Phage production ceases, however, as the cells enter the stationary phase. During an infection, a single cell can produce about 1,000 phage virions in 2 hours.

M13 has been of considerable biotechnical use, first for DNA sequencing and later in “phage display”.¹⁶⁹ Phage-display technology uses short peptides inserted into gp3 that are exposed on the surface of the phage and can be used as affinity probes. If a random sequence encoding the peptide is inserted into gene 3, the affinity of the best binding phages for a ligand can be selected. Applications in nanotechnology, in surface chemistry, and for medical and material science have shown the broad utility of this phage display technology.

The filamentous phage CTX ϕ phage of *Vibrio cholerae* is of considerable interest as it encodes the cholera toxin genes.¹⁸⁵

FIGURE 75.13. Secretion of M13. **A:** M13 phage secreted from *Escherichia coli* cells 9 minutes postinfection by atomic force microscopy. The bar represents 1 μm . **B:** Schematic model of M13 passing the inner membrane (IM) and outer membrane (OM) of the host envelope.

CTX ϕ phage encodes homologs of all M13 genes, except gene 4, which is replaced by the toxin genes *ctxA* and *ctxB*. Consequently, CTX ϕ phage uses the secretin EpsD in the outer membrane of *V. cholera* for traversing the outer membrane. To infect new host cells CTX ϕ phage uses a type IV pilus, the toxin co-regulated pilus (TCP), as a receptor. The pilus genes are localized in a pathogenicity island, which resembles elements of another filamentous prophage, VPI phage.⁹¹ CTX ϕ integrates into the chromosome of its host and CTX ϕ expression is regulated by the phage repressor, RstR. A second integrated filamentous satellite phage, called RS1, is involved in inducing CTX ϕ replication by binding of its antirepressor RstC to RstR.⁵⁰ The pathogenicity of *V. cholerae* is thus the consequence of a complex interplay between different filamentous phages.

Leviviridae: +ssRNA

The *Leviviridae* are the smallest of the known phages and the only ones with ssRNA in their virions.¹⁸⁴ The virion RNA is of the positive (i.e., mRNA) sense and encodes four genes, with functions that are described later. There are two slightly different varieties of these phages that have been well studied, one typified by phages MS2, R17, and others, with a genome length of ~3,500 bases, and a second typified by phage Q β , with a genome length of ~4,200 bases. These best-studied examples of this family of phages infect *E. coli*, but similar phages have been identified that infect a variety of other hosts, including gram-positive hosts, and virions of this family appear to be quite abundant in the environment.

The virion is a T = 3 icosahedral structure with 180 molecules of the “coat” protein and one copy of the “maturation” protein. The RNA is inside, and although it does not have the icosahedral symmetry of the protein capsid, a significant amount of RNA interacting with coat protein can be visualized in icosahedrally averaged cryo-EM structures of virions.⁹⁶ This indicates that there is significant order to the RNA within the virion. The coat protein has a fold that has not been seen in any other viruses, consisting of a β -sheet and a large α -helix. The subunits associate as dimers in which the α -helices are passed across the dimer twofold axis to link the two subunits by their α -helical “arms.” The dimer is the functional unit that assembles into the capsid.

Infection starts when the virion binds, through its maturation protein, to the side of the F pilus. The maturation protein becomes proteolytically cleaved and the RNA is released into an RNase-sensitive form, which transits to the cytoplasm of the cell. How this last step is accomplished is not clear, but it may involve retraction of the pilus. The maturation protein may have a role in guiding the RNA into the cytoplasm, but once it is there the RNA alone is sufficient to initiate the infectious cycle, as demonstrated by the fact that naked RNA can be electroporated into the cell to successfully initiate infection. The virion RNA and copies of it that are made subsequently serve as the mRNA for the virus. No subgenomic mRNA is made, yet there is substantial temporal and quantitative regulation of expression from the four genes. This is accomplished by a complex interaction of the extensive and dynamic secondary structure of the RNA with ribosomes and with the replicase.

The genes are arranged on the RNA in the order 5′–[maturation]–[coat]–[replicase]–3′. In MS2-type phages a fourth

gene, the lysis gene, overlaps both the end of the coat gene and the beginning of the replicase gene.⁶² When the RNA first enters the cell, its secondary structure allows productive binding of ribosomes only at the start of the coat gene. As ribosomes proceed through the coat gene they disrupt RNA secondary structure that is sequestering the start of the replicase gene, allowing other ribosomes to make replicase protein with delayed kinetics relative to coat. The phage-encoded replicase protein joins with three host proteins—translation factors EF-Tu and EF-Ts, and ribosomal protein S1—to constitute the four-subunit polymerase complex that copies the RNA. Replication is a conceptually simple synthesis of a (–) strand from a (+) strand template followed by synthesis of a (+) strand from a (–) strand template. Synthesis of (+) strands is more efficient than synthesis of (–) strands, in part because the polymerase has to compete with ribosomes for access to the (+) strands through a mechanism that prevents polymerase from synthesizing RNA in the 3′ to 5′ direction on the (+) strand template at the same time that ribosomes are synthesizing protein in the 5′ to 3′ direction. The translational start site for the maturation protein is always sequestered from ribosomes except for a brief period after that part of the mRNA is synthesized, before the secondary structure that hides the ribosome binding site forms. There is time for only about one ribosome to get on the mRNA before the secondary structure forms and the site is obscured; this means there is roughly one maturation protein made for every (+) strand RNA synthesized—just the ratio that is found in virions.

Progeny virions are assembled from 90 dimers of the coat protein, one molecule of the maturation protein, and one (+) strand RNA. Neither the coat protein nor the RNA will achieve their assembled configuration in the absence of the other. It has been shown that protein and RNA each interact with the other in ways that influence its conformation and assembly capabilities, in an intricate *pas de quatre-vingt-douze* leading to a mature infectious virion.¹¹ In phage MS2, the protein responsible for lysis is encoded by a gene that starts within the coding sequence of the coat gene, in a different reading frame. Ribosomes do not directly enter the start of the lysis gene; rather, the ribosomes that terminate at the coat gene termination codon remain associated with the mRNA, and a small fraction of them drift back by several nucleotides and initiate synthesis of the lysis protein.¹⁹⁸ Cell lysis occurs when the lysis protein has accumulated to a sufficient level, but the mechanism of lysis is unknown. In phage Q β the genes are organized slightly differently and there is no explicit lysis gene. Rather, lysis is caused by a portion of the maturation protein. In this case it has been shown that lysis is caused by inhibition of an enzyme in the cell wall synthesis pathway, MurA.¹⁴ This is similar to what is described earlier for the ϕ X174 E (lysis) protein, except that it targets a different step in the cell wall synthesis pathway.

At the time of the early studies of these phages, their virion RNA was the only prokaryotic mRNA available in pure, homogeneous form. As a result, it allowed the first view of what a translation start site looks like, as well as showing that some parts of an mRNA might not encode protein. In the time since, these viruses have provided extremely fruitful models for understanding how the structure and structural dynamics of RNA can influence and regulate biological processes of general importance, such as gene expression and virion assembly.

Cystoviridae: dsRNA, Segmented

Cystoviruses are unique phages that have a segmented genome composed of dsRNA and an envelope enclosing a viral nucleocapsid composed of two concentric protein shells and the genome.⁸ The viral envelope fuses with the outer membrane of the gram-negative host bacterium after receptor binding. The type member of the family *Cystoviridae* is *Pseudomonas* phage $\phi 6$, but other similar viruses have been isolated, all infecting gram-negative hosts, mainly in the *Pseudomonas* genus. The genome consists of three linear dsRNA molecules, 2,948, 4,063, and 6,374 bp in size, that encode 11 viral structural proteins and two nonstructural ones. The genes are clustered on the three genome segments according to their functions.¹⁴⁵ During the replication cycle the genome segments are converted into full-length polycistronic transcripts, each encoding four to five viral proteins. Noncoding regions at the 3' and 5' termini of the ssRNA molecules, flanking the internally located coding sequences, are approximately 370 and 310 nucleotides long, respectively. The sequence at the 5' end displays only limited homology (17 nucleotides identity) between the segments, while the untranslated regions at the 3' end are more similar to one another.¹²⁵

The innermost protein shell in the virion, the polymerase complex, is composed of four protein subunits. The major capsid protein P1 is arranged on an icosahedral T = 1 lattice so that a dimer of P1 occupies the asymmetric unit. Such capsid organization is also characteristic for the dsRNA viruses infecting eukaryotic hosts.¹⁴⁴ Hexamers of the packaging nucleoside triphosphatase (NTPase) occupy the fivefold symmetry positions, exterior to the P1 shell. The assembly co-factor P7 and the RNA-dependent RNA polymerase P2 are located within the interior of the P1 shell. The first detectable assembly intermediate formed during phage $\phi 6$ infection is an empty polymerase complex, procapsid.¹⁴⁵ The three genome segments are packaged into these capsids in single-stranded form. RNA encapsidation is dependent on the segment-specific packaging signals at the 5' termini of the viral ssRNA molecules and the activity of the packaging NTPase; it proceeds in an orderly fashion from the smallest to the largest genome segment.¹²⁵ The encapsidated ssRNA molecules are replicated within the polymerase complex into dsRNA form by the P2 polymerase utilizing a *de novo* initiation mechanism.¹⁸³ Efficient replication is dependent on 3' terminal replication signals. Following replication the polymerase produces new single-stranded mRNA molecules from these dsRNA segments using a semi-conservative strand displacement mechanism. During the encapsidation of the dsRNA genome the polymerase complex particle undergoes substantial conformation changes expanding the internal volume and making the particles compatible for nucleocapsid surface shell assembly.¹⁴⁵ The nucleocapsid surface shell follows T = 13 icosahedral symmetry and is made mainly of protein P8, which is essential during the virion entry to assist the polymerase complex particles through the host plasma membrane. The viral envelope containing four phage-encoded integral membrane proteins is derived from the host plasma membrane in a process that is dependent on the viral nonstructural protein P12. As a last step of the virion maturation, receptor-binding spike protein associates with the fusogenic protein embedded in the envelope.¹⁴⁵ The progeny virions are released from the infected cell by phage-induced host cell lysis.

Corticoviridae: dsDNA, Circular

Bacteriophage PM2 is the sole described member, and therefore the type organism, of the family *Corticoviridae*.⁶ The virion is icosahedral, with triangulation number 21. Its coat protein has the double β -barrel fold similar to that found in PRD1 (*Tectiviridae*). Consequently, also the virion architecture resembles that of PRD1 with an internal membrane.² The genome is represented in a tightly supercoiled circular dsDNA molecule of 10,079 bp, inside the membrane.¹¹⁶ Ten phage-encoded proteins have been identified as components of the virion: one making up the capsid shell and one forming spikes on the vertices of the capsid, and most of the others are membrane proteins. The lipids of the virion membrane are derived from the plasma membrane of the host cell, but curiously the relative amounts of the different lipids are significantly different from the average lipid composition of the host.¹⁰⁴

The host of PM2 is a marine bacterium of the genus *Pseudomonas*. Infection begins when the virion binds to a receptor on the cell surface leading to the release of the major coat protein and most possibly the virion membrane fuses with the host one.⁹⁴ Twenty-one protein-coding genes are inferred from the genome sequence, and the encoded proteins have been identified for 15 of them. The genes are organized into three operons. The *immediate early* operon has just three genes, is transcribed in the opposite direction to transcription of the other genes, and has sequence similarity to a region of a plasmid found in some *Pseudomonas* strains. The *early* operon encodes an apparent replication initiation protein and two transcription factors necessary for transcription of the *late* operon, which encodes the virion structural components. DNA replication is thought to occur by the rolling circle mechanism, based on EM views of replication intermediates, and this interpretation is bolstered by the similarity of the replication initiation protein to the corresponding protein of phages such as ϕ X174 (*Microviridae*), which is known to replicate its DNA by this mechanism. The mechanism of virion assembly is not well understood, but structures that appear to be membrane-enclosed DNA are seen associated with the cell membrane late in infection, and it is surmised that these are assembly intermediates around which the protein capsid assembles. In laboratory growth in rich medium, about 300 progeny virions/cell are released after a 60- to 70-minutes life cycle. The particles exit from the host utilizing a novel mechanism.⁹⁹ There is a new type of holin-like protein to permeabilize the plasma membrane, and PM2 seems to use a host-derived lytic enzyme to digest the peptidoglycan. There is also a viral protein that disrupts the outer membrane of the host, a function not described previously in phage release.

PM2 was the first bacteriophage shown to have a lipid membrane as part of the virion. It is noteworthy that PM2 was isolated in the mid-1960s yet no other examples of the family have been reported in the more than 40 years since. Very recently PM2-like sequences, which may be prophages, have been detected in the genomes of many marine bacteria.⁹⁸ This may mean that they are not that rare in the environment, and perhaps more plausibly it could mean that methods usually employed for isolating new phages fail to capture this group efficiently. This raises the question of how many novel groups of phages still await discovery.

Plasmaviridae: Circular dsDNA

The *Plasmaviridae* are a small family of phages in which the few known examples infect members of the bacterial genus

Acholeplasma, a member of the mycoplasma. Most of the work on the group has been done with phage L2. The genome of L2 is found in the virion as an 11,965-bp circular, supercoiled dsDNA molecule.¹¹⁵ Fifteen protein-coding genes have been deduced from the sequence, including at least four that encode components of the virion and one that encodes an integrase. The virions are small, quasispherical, somewhat pleomorphic structures, consisting of a membrane envelope surrounding the DNA. The locations of the viral proteins in the structure are not known.

Phage L2 has an unusual life cycle in which, instead of making a decision between lytic and lysogenic modes of growth, it does both every time it infects. That is, the first part of the life cycle is productive, producing virions that leave the infected cell by budding, without killing the cell. This is followed by the lysogenic phase in which virion production ceases and the phage DNA integrates into the host chromosome by a site-specific recombination event, apparently catalyzed by the phage integrase. Prophage-containing cells are immune to infection by homologous but not heterologous phages of the family, and lytic growth of the prophage can be induced by UV or mitomycin treatment. These observations are suggestive of a phage-encoded repressor analogous to those of phages like λ .

EVOLUTION OF PHAGES

Genome Mosaicism

How phages evolve has been a long-term interest in the field, and the scope and specificity of what can be learned have expanded greatly with the availability of high-throughput DNA sequencing. To somewhat oversimplify, phages have been used in two ways in evolutionary studies. In the first, phages are put into a controlled environment in the laboratory and followed by genome sequencing through various selections, competitions, population bottlenecks, and so forth. This approach has allowed rigorous testing of a number of different aspects of evolutionary theory and made it possible to elucidate specific pathways of adaptation, typically at the single nucleotide level, and in this way to illustrate individual evolutionary events that must take place in natural phage evolution. This work has been very valuable but has not necessarily represented most of the enormous and chaotic complexity of the natural environments where phages evolve nor the extraordinarily long times over which phage evolution is thought to have occurred, and it will not be discussed further here. The goal of understanding the mechanisms of evolution as actually practiced by phages has been more closely approached by isolating phages from the environment and sequencing and comparing their genomes.⁷² This approach has the limitation that the sampling of the population is extremely sparse and almost certainly biased, but it has nevertheless yielded a wealth of information about the structures of the genomes produced by phage evolution, and this has allowed inferences about the mechanisms by which they got there. In thinking about phage evolution it is helpful to keep in mind the numbers cited in the first paragraph of this chapter. For example, there are $\sim 10^{24}$ infections per second on a global scale for the tailed phages alone (see earlier), and each of those infections is an opportunity for genetic mischief. As we describe later, there is reason to believe that this has been going on for something like the past 10^{17} seconds. Most of the

discussion given later relates to the tailed phages, for which the most information is available; there is also some comparable work available for the *Microviridae*, which has produced similar but not identical conclusions about mechanisms in this different group of phages.

If the genomes of a closely related group of tailed phages are compared, they are seen to be genetic mosaics with respect to each other. That is, the sequences of two genomes may be nearly identical over the length of a few genes and then abruptly change so that they match less well or not at all.^{32,80} These sites are the “fossils” of nonhomologous recombination (i.e., recombination between two DNA sequences that are different from each other) in the ancestry of one of the phages, creating a “novel joint” in the genome such that two sequences are placed adjacent to each other that were not adjacent in either parental sequence.¹³⁷ This is the mechanism by which these phages are thought to achieve horizontal exchange of DNA sequences, and horizontal exchange is a central feature of the evolution of these phages. The locations of the novel joints are informative; in most cases they have recombined between genes or at gene boundaries. This was initially thought to suggest that recombination events occurred preferentially at gene boundaries.¹⁷⁵ However, closer examination of the data argues that nonhomologous recombination occurs promiscuously across the entire genome without site specificity, but that the vast majority of recombinants are eliminated by natural selection. The recombinants that survive are those that do not disrupt function, and most of these are at gene boundaries, or in other words, not within protein-coding regions. The exceptions that prove the rule are novel joints that fall within protein-coding regions but at positions corresponding to functional domains of the protein. The tyrosine integrases, tail fibers and tail-spikes, and DNA packaging proteins provide good examples of this. Opportunities for recombination between different phage genomes arise when a cell is infected simultaneously by two phages; however, a more frequent opportunity for recombination occurs when the infected cell carries one or more prophages, as is likely true for a great majority of cells.³⁰

Homologous recombination (i.e., between identical sequences) also certainly has a significant role in the reassortment of genes among genomes in that homologous recombination between identical sequences on different genomes can reassort the novel joints and dissimilar genes that flank the identical sequences. These identical sequences may be identical protein-coding sequences. In addition, there are scattered examples of identical stretches of sequence shared between intergenic regions, and more generally, intergenic regions may share more than random sequence similarity due to shared occurrence of transcription and translation signals, and this may bias recombination toward these locations.⁴⁰

There are apparent constraints beyond those described earlier on where recombination between genomes can occur (and survive natural selection to be seen by us). Thus, in the smaller tailed phages like λ and its relatives, there is little or no mosaicism seen within the group of procapsid assembly genes and usually also little mosaicism within the group of tail tip assembly genes. Similarly, genes for DNA binding proteins, for example, the λ *cI* repressor gene, “travel through evolution” together with the DNA sites their encoded protein binds. Such cases are thought to be explained by shared function of the genes that show this behavior. Thus, the proteins encoded by

the head genes of a phage like λ must each interact intimately with the other head proteins during head assembly and in the assembled structure, and they have co-evolved over time to maintain productive interactions among the group. Substitution of a homologous gene or genes from a phage that had followed a different path of mutation and co-evolution would in almost all cases be expected to produce a nonfunctional set of head genes and be counterselected, even though all the genes would be functional in their home genomes. A notable exception to such co-evolution is the parts of tail fiber and tailspike genes that bind bacterial receptors. They appear to have been horizontally exchanged many times among even very different phages. For example, there are members of the *Podoviridae*, *Siphoviridae*, and *Myoviridae* that, in spite of having very different life cycles, have nearly identical tailspikes that utilize the same host receptors. It seems that sometimes when a phage manages to obtain a new host specificity in this way, it can have an advantage, because it can enter an evolutionarily naive cell that is not prepared to defend itself against a phage that it has not “seen” before.

Common Ancestry of Archaeal and Eukaryal Viruses with Phages

Homology (shared ancestry) among viral genes can be inferred from similarity of their encoded amino acid sequences, as is done routinely, for example, for genes of mammalian genomes. However, this approach has turned out to be quite limited for viral sequences because the sequences of viral proteins that are thought on other grounds to be homologs have often diverged to the point that they can no longer be recognized as similar. This has meant that, while it is possible to construct phylogenetic trees based on protein sequences from closely related viruses, there is little hope of inferring the deep evolutionary history of viral proteins or their associated viruses based on sequence comparisons alone. Happily, this situation has changed somewhat with the advent of structural information about viral proteins—mostly virion structural proteins—in recent years.

The capsid *hexons* of bacteriophage PRD1 (*Tectiviridae*) are homotrimers of a protein subunit that has two domains, each of which is a β -barrel of the *jelly-roll* type.⁷ Each of the jelly-rolls occupies a position in the capsid lattice that would be occupied by a single capsid protein subunit in a classical Caspar-Klug structure. The high-resolution structure of the PRD1 hexon was a surprise when it was first determined because the aforementioned description applies equally well to the hexons of adenovirus.¹² The similarity extends to the protein folds of the two hexon proteins, and this has led to the inference that these two proteins may share common ancestry, despite the fact that their amino acid sequences no longer share any detectable similarity. The same double jelly-roll fold has been found subsequently in eukaryal viruses PBCV1 (*Phycodnaviridae*) and Mimivirus (*Mimiviridae*); *Sulfolobus* turreted icosahedral virus (STIV; *Rudiviridae*), which infects the hyperthermophilic archaeon *Sulfolobus*; and bacteriophage PM2, arguing that this diverse and sequence-dissimilar group of capsid proteins also shares in the PRD1 and adenovirus ancestry.

The tailed phages (*Caudovirales*) have a capsid protein with a very different fold, typified by that of *E. coli* phage HK97.¹⁹¹ Evidence to date indicates that this fold is shared across all of the tailed phages, including those that infect archaeal hosts,

often in the absence of detectable sequence similarity. It also appears that this same “HK97 fold” makes up the shell-forming domain of the herpesvirus capsid protein, arguing for a common ancestry with the tailed phage capsid proteins for the herpesvirus protein as well.⁸⁸ The case for common ancestry between tailed phage and herpesvirus capsid proteins is bolstered by shared mechanisms of capsid assembly and DNA packaging, including faint but convincing sequence similarity between the DNA-packaging proteins of phage T4 and herpes simplex virus. A third capsid protein fold reaching across host domains includes phage $\phi 6$ (*Cystoviridae*) and the reoviruses of plant and animal hosts. These viruses have double protein shells; the inner shell has the noncanonical $T = 2$ structure with a novel protein fold and the outer shell is a $T = 13$ shell of single jelly-rolls.¹⁴⁴ Together these observations lead to the view that these viruses define at least three viral lineages, or perhaps more properly three viral capsid lineages, whose hosts span all three domains of cellular life (Fig. 75.14). A simple (but not yet firmly established) interpretation is that viruses with the basic capsid characteristics of these contemporary viral lineages had already evolved by the time of the last common cellular ancestor of the cellular domains of life. There are of course viruses with icosahedral capsids but without any of the capsid protein folds of these three lineages, for example, the *Leviviridae* (small ssRNA genomes) among phages. The capsid protein folds associated with these other viruses are thus far associated only with hosts within one cellular domain, and it will be interesting to see how that situation changes as more viruses are identified and characterized. There are also other examples of virion protein structural similarities among very different virus types. For example, fibers that protrude from the icosahedral vertices of adenoviruses and tectiviruses, as well as fibers that extend from some phage tails, have knobs at the distal tips. The polypeptide folds of these three knobs are sufficiently similar to suggest a possible common ancestry.¹⁷

PHAGE PARTS IN OTHER CONTEXTS

Structures are occasionally found in bacterial or archaeal cells that bear a structural resemblance to virions—or parts of virions—of the tailed phages. For the examples given here, examination of the polypeptide folds of the components of the structures, and in most cases, comparisons of their amino acid sequences, makes a strong case for common ancestry shared by the virions of tailed phages and these “cellular” structures.

Pyocins

The pyocins are a class of high-molecular-weight bacteriocins encoded in the genomes of some *Pseudomonas* strains.¹²³ They have the morphology of phage tails, either contractile or not, and they kill sensitive cells after they are released from the cell that encodes them, apparently by making holes in the cell envelope and causing collapse of the cellular membrane potential. The genes encoding the pyocins have close sequence similarity to the tail gene operons of well-studied phages—*E. coli* phages P2 (contractile tail) and λ (noncontractile tail), respectively—in the well-characterized cases of the R2 and F2 pyocins of *P. aeruginosa*.¹²³ The high sequence similarity between the respective pyocin and phage tail operons bespeaks an evolutionarily recent common ancestry.

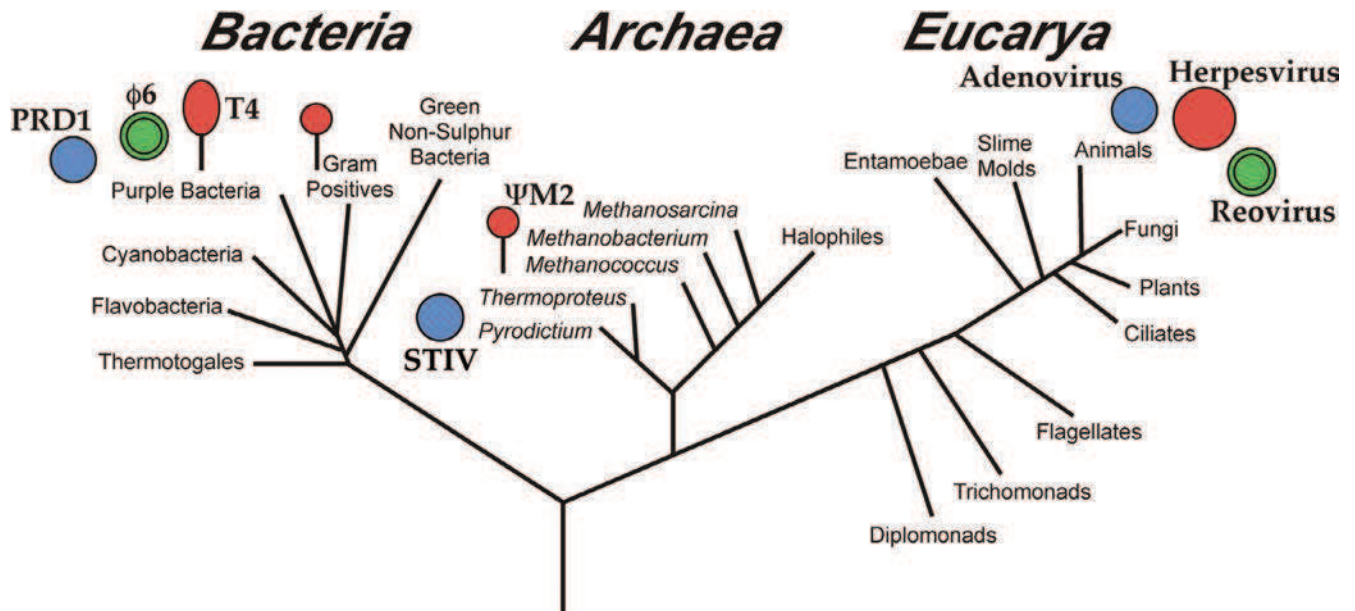

FIGURE 75.14. Deep evolutionary connections among viruses. The tree represents the tree of cellular life. The colored symbols represent the indicated viruses, placed near their cellular hosts. Shared color indicates shared “viral lineage”, as deduced from shared structural features of the virions.

Gene Transfer Agents

Gene transfer agents, or GTAs, were discovered as a generalized transducing activity in cultures of *Rhodobacter capsulatus*.¹⁰⁸ They were subsequently shown to be small particles with the morphology of a tailed phage that package short (4.5-kbp) pieces of DNA derived from apparently random locations around the *R. capsulatus* genome. GTA-like particles with similar properties have been identified in several other bacterial and archaeal species, but the *R. capsulatus* GTAs are the best characterized. The GTA particles are encoded by a ~14-kb-long operon of genes in the *R. capsulatus* genome. In both gene organization and sequence similarity, the genes of this operon strongly resemble the head and tail genes of a tailed phage with a noncontractile tail. The GTA operon bears some resemblance to a prophage, and it may well have derived from one, but it is not a conventional prophage that has suffered deletion of its nonvirion assembly genes for at least two reasons. First, the heads of the particles can only package the equivalent of about one-quarter of the genes that encode the particle. Second, expression of the GTA genes is under the control of a cellular two-component system that senses conditions outside the cell. It appears that the cell may have co-opted the GTA genes to serve its own purpose. What that purpose might be is not known, but a plausible possibility is that the GTA particles are genetic repair kits, sent from one cell to other cells in the population, to save the population from the ravages of Müller's ratchet.

Encapsulins

The encapsulins are a recently described group of subcellular shells found in both bacteria and archaea.⁴⁴ In cases where their function has been inferred, they enclose and sequester biochemical reactions that produce potentially harmful reactive intermediates. The shells are icosahedral structures, $T = 1$

or $T = 3$, made of protein subunits that bear clear homology to the phage HK97 family of capsid proteins, based both on close structural similarity and on a low but unequivocal level of amino acid sequence similarity. The genes encoding the encapsulin subunits are not associated with any other phage-like genes in the cellular genome.

Type VI Secretion Systems

Recent structural studies of the proteins of the needles of the *Pseudomonas* and *Edwardsiella* type VI secretion systems (T6SS) show that the major subunits of the needles have the same polypeptide fold as the tail tube protein of phage T4 (gp19), despite a lack of recognizable shared sequence.⁸⁷ This is taken to suggest a common ancestry for the two proteins and, by extension, possible common ancestry for the phage tail and the T6SS apparatus.¹⁰ A parallel study with the phage λ tail tube subunit, gpV, shows that it shares the gp19 fold, arguing that the common ancestry inferred for the tail tube of a contractile tailed phage and the T6SS needle extends to the noncontractile phage tails as well.¹³⁹ Recent structural studies have identified a long contractile structure, resembling an exceptionally long contractile phage tail, in cells indulging in type VI secretion¹⁰⁷ (Fig. 75.15). This structure assembles in the bacterial cell as it is preparing for secretion and disassembles after. It appears to drive the T6SS needle into the target cell by contraction of the sheath, just as a contractile phage tail drives the tail tube through the envelope of a target bacterium.²⁹

In all of these cases there seems little doubt that the structural proteins of phages and the corresponding proteins of phage-like structures in bacterial and archaeal cells share common ancestry. A simple and generally accepted explanation for this relationship is that a group of phage genes has been captured by the host cell, possibly from a resident prophage, and placed under a regulatory scheme that benefits the host. In this

FIGURE 75.15. Structure of the bacteriophage T4 baseplate and comparison of the *Escherichia coli* CFT073 c3393 VgrG with its T4 homologs, gp5 and gp27. Cryoelectron microscopy (cryo-EM) reconstructions of the T4 baseplate before (A) and after (B) attachment to the host cell. Component proteins are labeled with their respective gene numbers. The T6SS protein homologs are highlighted in bold and underlined. C: The crystal structure of the c3393 VgrG. Different domains are colored in distinct colors. The gp27 tube domains are colored cyan and light green. The fragment of the polypeptide chain connecting the gp27 and gp5 modules is shown as a thick red tube. D: The structures of gp5 and gp27 monomers extracted from the (gp5)₃–(gp27)₃ complex. The terminal ends of the gp5 and gp27 polypeptide chains, which become fused in the VgrG structure, are highlighted with red dots. E: A model of the prototypical VgrG is created from the entire (gp5)₃–(gp27)₃ complex by removing the lysozyme domain. F: End-on view of the crystal structure of the c3393 VgrG trimer. (From Leiman PG, Basler M, Ramagopal UA, et al. Type VI secretion apparatus and phage tail-associated protein complexes share a common evolutionary origin. *Proc Natl Acad Sci U S A* 2009;106:4154–4159, with permission.)

view, such acquisition of phage virion structural genes is simply an example of the more general phenomenon of cells acquiring “phage” genes and converting them over time into “cellular” genes. The difference in the case of the structural genes is that they are more easily recognized as being of phage origin, even after mutational drift has eliminated any detectable sequence similarity. However, despite the plausibility of tailed phages as the progenitors of the cellular structures enumerated earlier, there is no formal proof that the arrow might not go in the other direction—that is, that T6SS needles, for example, might be the ancestors of phage tails!

HOST INTERACTIONS

The essence of being a virus is interacting with the host, and these interactions influence both virus and host. We will consider some examples of interactions between phages and bacteria in three somewhat artificial and overlapping categories.

Parasitic Interactions

Phages hijack their hosts’ biochemical machinery, usually to the detriment of the host, and as in other areas of virology, understanding how these interactions work often tells as much about the cell as about the virus. The ways these interactions are carried out are as varied as the phages doing them; we give examples here of some of the better-studied cases.

DNA Replication

Some phages such as phage T4 encode all the proteins needed to replicate the phage genome. These form a complex that replicates the phage DNA with a preference for the modified cytosine nucleoside that T4 uses in place of cytosine. At the same time other phage-encoded enzymes are degrading the host DNA and recycling the nucleotides (in conjunction with some host nucleotide metabolism enzymes) for use by the phage replication machine. *Bacillus* tailed phage SPO1 has at least nine genes required for phage DNA replication but appears to be lacking some of the complete set of replication genes that a phage like T4 has.¹⁷⁰ SPO1 uses hydroxymethyl uracil in its DNA in place of thymine, and the phage encodes several enzymes with roles in depleting thymine pools and synthesizing hmU, and the phage-encoded DNA polymerase has an extra domain that is proposed to help it recognize the hmU-containing template. Many phages use the complete host replication machinery, synthesizing only the proteins needed to recruit the replication complex to the phage DNA template. An example is phage λ , which makes two replication-specific proteins, one of which (gpO) binds the phage replication origin and one (gpP) that recruits the host replication helicase, and through it the rest of the host replication complex, to the phage origin.¹⁷⁸ Unlike T4, λ does not degrade the host DNA, presumably because doing so would preclude the possibility of forming a lysogen. Phage ϕ X174 also uses the host replication machinery. However, unlike the host and unlike most other phages, it uses the host transcription RNA polymerase to lay down the RNA primers at the start of new DNA chains, rather than primase, the specialized RNA polymerase that usually carries out the priming function. For technical reasons, this peculiarity of ϕ X174 facilitated the original discovery that RNA primers have a role in DNA replication. The ssRNA

phage MS2 encodes a replicase protein, but to replicate the RNA it co-opts the activities of three cellular proteins (EF-Tu, EF-Ts, S1) that normally interact with RNA but to very different ends.

Transcription

Most DNA phages use the host RNA polymerase for some or all of their transcription. They often achieve temporal separation of different classes of transcripts by successive modifications of the host polymerase. For phage λ the transition from *immediate early* to *early* transcription is mediated by the immediate early antitermination protein gpN, which interacts with the nascent RNA transcript and the RNA polymerase to render the polymerase able to read through termination signals.¹⁵⁴ The transition from *early* to *late* transcription is mediated by another antitermination protein gpQ, acting by a different mechanism. Phage T4 makes covalent modifications to the host polymerase early in infection and adds a phage-specific sigma factor to the polymerase to effect the transition to late transcription.⁸² Phage T7 transcribes its early genes with the host RNA polymerase, but one of these genes encodes the phage RNA polymerase, which is responsible for subsequent transcription of phage genes. Another early gene of T7 encodes a kinase that inactivates host transcription by phosphorylation of the host RNA polymerase.¹²² A phage that flouts all the normal conventions for organizing transcription is *E. coli* phage N4. N4 packages a few copies of a *virion RNA polymerase* in the virion with the DNA, and they are injected into the cell along with the DNA.⁵² The virion RNA polymerase transcribes the early genes, some of which encode a second (phage-encoded) RNA polymerase that transcribes the middle genes. The middle genes include genes supporting phage DNA replication and also an ssDNA binding protein, which interacts with the late promoters in such a way that they can be read by the unmodified *E. coli* σ^{70} -RNA polymerase!

Translation

All phages, like all viruses, use the host translation apparatus to make their proteins. For the most part the phages appear to use it in unaltered form, though they do make use of some of the “special abilities” that ribosomes have beyond the textbook descriptions of translation. These include programmed translational frameshifts (many phages), a 50-nt ribosomal “hop” (phage T4), a few examples of regulation of gene expression at the level of translation (phage T4), and the extensive examples of regulation of translation described earlier in the section on the *Leviviridae* (the ssRNA phages).^{84,196} For many tailed phages, particularly (but not exclusively) those with larger genomes, there is suggestive evidence that they also make specific alterations to the host translation apparatus. The most frequently encountered support for this assertion is in the form of phage-encoded tRNAs. Although the majority of characterized phages do not encode any tRNAs, there are many that do. The numbers of apparent tRNAs per genome in this group range from 1 to greater than 30, with their genes usually arranged in one or more clusters on the genome. Some of these putative tRNAs give high scores in tRNA search programs trained on cellular tRNAs and some do not, and in only a few cases have they been tested and shown that they can actually function as tRNAs. It has been suggested that the purpose of the phage-encoded tRNAs is to adjust the tRNA pools in the infected cell

to better serve the needs of phage translation, but they may have other roles that are not yet identified. Several phages have been found to carry a copy of a transfer-messenger RNA (tmRNA), the RNA found in prokaryotes with features of both tRNA and mRNA and a role in releasing stalled ribosomes from mRNA. Finally, phage G of *Bacillus megaterium*, the phage with the largest genome known at 498 kb, has one aminoacyl tRNA synthetase.⁷⁵ This last feature is reminiscent of the very large Mimiviruses, which also carry aminoacyl tRNA synthetases for which the biological role also is not known.⁴² These observations taken together make a strong case that some phages modify the host translation machinery, but there is as yet little specific information about how or to what end they might actually do this.

Other Cellular Machinery

Phages rely on their hosts for energy metabolism. They also typically use the cellular biosynthetic machinery to make precursors for macromolecular synthesis, but a number of phages encode enzymes with roles in nucleotide metabolism. When these are present they typically act in conjunction with cellular enzymes of nucleotide metabolism. Two of the most easily recognized and frequently found nucleotide metabolism genes in phages encode ribonucleotide reductase and thymidylate synthetase. To date, there is no evidence of phages participating in amino acid biosynthesis, nor of phages incorporating noncanonical amino acids into their proteins. For phages with lipid membranes in their virions, the lipids appear in all cases to be derived from the cellular membrane.²

Phages also make use of host chaperone proteins, and in fact some of the most important of these were discovered because of their roles in the life cycles of phages λ and T4. The *E. coli* DnaK and DnaJ proteins (also known as Hsp70 and Hsp40) were found to be required for λ DNA replication, where they partially disassemble the replication initiation complex and allow the replication machinery to leave the origin and begin synthesis. GroEL and GroES (Cpn60 and Cpn10) are required for accurate assembly of phage λ heads, now understood as a consequence of their role in mediating correct folding of some of the head proteins. GroEL is also required for phage T4 head assembly because of its role in folding the major capsid protein gp23. The gp23 subunit is apparently slightly too big to fit into the GroE folding cavity with the GroES “lid” in place, and T4 encodes its own homolog of GroES, gp31, which leaves enough more space in the cavity for successful folding of gp23. We note that these two chaperones, now known as the hsp70 (DnaK) and hsp60 (groE) systems and known to be very important and present in virtually all organisms, were originally discovered in work designed to understand the molecular nature of these phage infections.

Phages interact in significant ways with cellular structures, particularly the cell wall and membranes, during cell entry and exit. The *Leviviridae* (ssRNA, icosahedral) and *Inoviridae* (ssDNA, filamentous) of *E. coli* bind to the sides and tip, respectively, of the F pilus, and they are thought to be brought to the surface of the cell for further interactions by retraction of the pilus. The tailed phages Cb13 and CbK of *Caulobacter crescentus* have helical tail fibers that wrap around the shaft of the bacterial flagellum.⁶⁹ This makes an interaction that is apparently able to slide along the helical flagellum, and when the flagellum rotates in the appropriate direction the phage is

screwed down to the surface of the cell where it interacts with a cell surface receptor.

Antagonistic Interactions

Phages and their bacterial hosts engage in ongoing “biological warfare” in which mutations arise in the bacterium that block successful lytic growth by the phage, which in turn creates a selective advantage for phages with mutations that overcome the block. The best-known examples are mutational changes that affect the binding between the virion and its receptor on the surface of the cell. In the tailed phages, a single amino acid change in the tail fiber protein can be sufficient to restore binding to a recalcitrant cellular receptor, but bigger changes occur as well. The parts of tail fiber genes that encode the receptor-binding part of the tail fiber often show evidence of recent horizontal exchange, and in some phages rapid changes of sequence, specifically in tail fibers, are programmed into the phage genome, as in the examples of phage Mu and phage BPP-1.^{119,163} The biological warfare continues after the phage has successfully gotten its genomic DNA or RNA into the cell. Many examples could be given; a particularly piquant example comes from the *prcC* gene of *E. coli*. The product, PrrC, is a nuclease that cuts in the anticodon loop of the cellular tRNA^{Lys}, inactivating it and so inhibiting protein synthesis in the cell.¹⁸² PrrC is ordinarily held in an inhibited form, but infection by phage T4 causes its release in active form, whereupon it cleaves this tRNA. The “purpose” of the cleavage is evidently to prevent the phage from making virions that could infect other cells in the population. However, T4 encodes two enzymes, polynucleotide kinase and RNA ligase, that counter this host defense by repairing the tRNA. Relatives of T4 that lack the repair enzymes are unable to grow on *E. coli* strains that carry *prcC*. A more widely distributed host defense is the CRISPR system, sometimes referred to as bacterial (and archaeal) adaptive immunity.⁵³ Cells with a CRISPR system have a mechanism to collect an array of short (~25-bp) DNA sequences derived from phages of past infections (which the ancestral cells evidently survived). When a phage that has an exact match to one of the sequences in the CRISPR array infects, it is inactivated by a mechanism that may have some features in common with the eukaryotic small interfering RNA (siRNA) mechanism. Phages can escape CRISPR surveillance if they acquire as little as a single nucleotide change in the sequence being recognized.

Symbiotic Interactions

When a phage enters the lysogenic cycle and becomes a prophage, most of the genes are repressed by the repressor protein. However, some phage-encoded proteins continue to be made from the repressed prophage—most obviously the repressor protein itself—and the list of other proteins expressed from an otherwise repressed prophage is growing.²¹ These proteins all have the potential to cause lysogenic conversion of their host cell, that is, a change in cell phenotype as a consequence of the protein's expression. In many cases the biological function of these lysogenic conversion genes is not known, but when it is, it can typically be construed as providing a selective benefit to the host cell in which the prophage resides. Thus, the phage λ prophage expresses the repressor and three other proteins, SieB, RexA, and RexB, each of which protects the cell from infection by certain other phages, and it also expresses two

proteins, Bor and Lom, which are thought to make the lysogenic cell better able to parasitize a mammalian host.⁹ Other such proteins are described later. It has been suggested that these lysogenic conversion genes do not provide a selective benefit to the phage directly but instead provide a selective benefit indirectly by providing a direct benefit to the lysogenic cell in which the prophage is being replicated. In other words, the lysogenic conversion protein is the rent the prophage pays to its host. It may also be that lysogeny provides a rather efficient pathway for the bacterium to acquire novel beneficial genetic functions. That is, as random deletions occur over time in the bacterial chromosome, any that remove one of the beneficial lysogenic conversion genes will be counterselected, whereas deletions that remove other parts of the prophage will be either neutral or selected. Over time only the beneficial genes will remain as part of the bacterial genome.

One of the best-studied groups of lysogenic conversion genes is the group of prophage genes known to encode toxins produced by bacterial pathogens.²⁸ The toxins of the human diseases botulism, diphtheria, cholera, and hemolytic uremic syndrome (HUS), among others, and the animal disease ovine foot rot, are encoded by prophage genes. The Shiga-like toxin encoded by *E. coli* 0157:H7, the causative agent of HUS, is of particular interest. This toxin is expressed at low levels from its own promoter, but the higher levels of toxin required to produce severe disease are only made when the prophage is induced and the toxin is produced under the control of the phage's strong late promoter.¹⁸¹ Some antibiotics cause induction of this prophage, and for this reason antibiotic treatment is contraindicated for this infection. The cholera toxin case is also noteworthy in that the toxin is carried on a prophage of a filamentous ssDNA phage of the *Inoviridae* family.⁵¹ All the other known examples involve prophages of the tailed dsDNA phages of the *Caudovirales* order.

Because studies of lysogenic conversion have been carried out by human biologists, it is not surprising that some of the best-studied examples of lysogenic conversion involve toxins of human pathogens. However, it is unquestionably true that there are prophages supplying selectively beneficial functions to their host bacteria (and host archaea) in virtually all of the ecological situations where these cells find themselves.

PHAGE COMMUNITIES AND ECOLOGY

Every gram of soil and sediment, every milliliter of water, and the surfaces and insides of plants and animals are hosts to extensive and diverse phage and bacterial communities. We now know that these environmental phage communities contain most of the uncharacterized genetic diversity on Earth. And because of their rapid killing of large numbers of bacteria, they strongly influence the flow of carbon, phosphorus, and other elements within the biosphere.

Metagenomic analyses of viral communities, also called viromes, have shown that 1 kg of marine sediment may contain over a million different phage genotypes (roughly equivalent to a species).¹⁹ Similarly, there are hundreds of thousands of viral species in the ocean and soils.⁶¹ Viromes from stool samples show that most of the genomic differences between individual humans are gut-associated phages.¹⁵² There are even phages in our blood.⁶⁴

Phage could potentially protect against pathogens by killing them, but phage may actually be the causes in others. For example, many bacterial pathogens are actually lysogens and their prophages carry the disease-causing genes. For example, the common mouth microbe *Streptococcus mitis* carries the prophage SM1. When induced, the phage SM1 virions carry modified tail fibers known as pblA and pblB, which “glue” *S. mitis* cells together and to platelets. If this happens in the blood, say, after tooth cleaning, then the phage–platelet–microbe blob can cause endocarditis. Scarily, the phage SM1 is induced by soy sauce and other more commonly ingested substances; eat up!¹⁹⁴

Bacterial communities in the environment are often controlled in a top-down manner; that is, there is more food available than the microbes use.^{48,192} This occurs because they are killed off by phage and other predators like unicellular protists. The continuous predation by phage leads to “kill the winner” dynamics, where one phage kills so much of a particular bacterial strain that another strain grows up in the unoccupied niche. This means that the dominant bacterial strain within an ecosystem will be constantly changing. Recent work has shown that kill-the-winner dynamics does not change the species of bacteria; rather, it causes cycling of different strains.¹⁵⁶

Our understanding of phage in the environment is in its infancy. At this point we know that there are almost unimaginable numbers of them, and they contain most of the uncharacterized genomic diversity on the planet. It is clear that to maintain the observed steady state, phages are influencing both the types and replication of bacteria, and it is also clear that there is an amazing, essentially unexplored world of phage diversity to be studied.

ACKNOWLEDGMENTS

I am extremely grateful to the following colleagues who contributed to this work when an unfortunate accident prevented me from completing it: Dennis Bamford (*Tectiviridae* and *Corticoviridae*), Sherwood Casjens (P22, P1, and N15), Gail Christie (P2 and P4), Eric Miller (T4), Bob Duda (HK97), Paul Jardine and Shelley Grimes (φ29), Andreas Kuhn (*Inoviruses*), Minna Poranen (*Cystoviridae*), Forest Rohwer (communities and ecology), and Graham Hatfull. I am also grateful to the following for assistance with figures: Sankar Adhya, Anastasia Aksyuk, Nicola Ambrescia, Ben Fane, Andrey Fokin, Burton Guttman, Betty Kutter, Petr Leiman, and Dale Lewis.

Conclusions

- Wider Spectrum of Neurodegenerative Diseases Caused by Prions

Acknowledgments

Prions are infectious proteins that have been identified in both mammals and fungi. That prions are composed solely of proteins makes them unprecedented infectious pathogens. Prion proteins can adopt at least two different conformations; prions multiply by forcing the precursor protein to adopt an alternative conformation. The replication of prions is a self-propagating process, in which the prion isoform imposes its structure on the nonprion, precursor form of the protein. Prion-mediated conformational changes can function as robust epigenetic switches that modify protein functions and cellular phenotypes as well as cause fatal diseases. Different conformations of proteins in the prion state encipher distinct strains and are prone to aggregation. In mammals, some prions accumulate to high levels in the central nervous system (CNS) where they cause dysfunction and fatal degeneration.

Both mammalian and fungal prions have been produced in cell-free systems. Synthetic prion protein (PrP) peptides

TABLE 76.1 The Prion Diseases Caused by the Prion Protein

Disease	Host	Mechanism of pathogenesis
Kuru	Fore people	Infection through ritualistic cannibalism
Iatrogenic CJD	Humans	Infection from prion-contaminated HGH, dura mater grafts, and so on
Variant CJD	Humans	Infection from bovine prions
Familial CJD	Humans	Germline mutations in PrP gene
GSS	Humans	Germline mutations in PrP gene
FFI	Humans	Germline mutations in PrP gene (D178N, M129)
Sporadic CJD	Humans	Somatic mutation or spontaneous conversion of PrP ^C into PrP ^{Sc}
sFI	Humans	Somatic mutation or spontaneous conversion of PrP ^C into PrP ^{Sc}
Scrapie	Sheep	Infection in genetically susceptible sheep
Bovine spongiform encephalopathy	Cattle	Infection with prion-contaminated MBM
Transmissible mink encephalopathy	Mink	Infection with prions from sheep or cattle
Chronic wasting disease	Mule deer, elk	Unknown
Feline spongiform encephalopathy	Cats	Infection with prion-contaminated bovine tissues or MBM
Exotic ungulate encephalopathy	Greater kudu, nyala, oryx	Infection with prion-contaminated MBM

CJD, Creutzfeldt-Jakob disease; FFI, fatal familial insomnia; sFI, sporadic fatal insomnia; GSS, Gerstmann-Sträussler-Scheinker disease; HGH, human growth hormone; MBM, meat and bone meal.

and recombinant (rec) PrP fragments have been used to form mammalian prions, whereas prion domains that are rich in glutamine and asparagine have been used to form fungal prions.

Although the PrP prions causing disease in mammals are infectious in the sense that they spread from cell to cell as well as from host to host, some prions do not move between cells, as in the case of yeast prions, and still others do not spread from one host to another as in the case of tau prions. In yeast, prions are clearly transmissible from mother to daughter cells but not between nondividing cells. Recent studies have demonstrated that several different proteins, each of which becomes a prion, cause distinct neurodegenerative diseases.

In mammals, PrP prions cause a group of invariably fatal, neurodegenerative diseases. Prion diseases may present as genetic, infectious, or sporadic disorders, all of which involve modification of PrP. The tertiary structure of PrPs is profoundly altered as prions are formed, and as such, prion diseases represent disorders of protein conformation. Creutzfeldt-Jakob disease (CJD) generally presents as a progressive dementia in humans, whereas scrapie of sheep and bovine spongiform encephalopathy (BSE) usually manifest as ataxic illnesses (Table 76.1).

A common feature of prions is the conformational transition of a precursor protein from a monomer to an oligomeric form. Although few proteins undergo the structural changes that transform them into prions, the prion precursor generally is a monomeric protein, but some precursors are multimers, such as the cellular PrP (PrP^C) dimer or the α -synuclein tetramer.^{19,183,251} Once formed, prion oligomers appear to bind

to other precursor protein monomers or multimers and induce the conformational change, thereby creating a self-propagating process. PrP oligomers possess a high β -sheet content and are more stable than the precursors; prion oligomers polymerize into amyloid fibrils.^{280,311,315}

PRIONS ARE INFECTIOUS PROTEINS

Mammalian prions reproduce by recruiting PrP^C and stimulating its conversion into the disease-causing isoform (PrP^{Sc}) (Table 76.2). PrP^C has a high α -helical content and little β -sheet structure, whereas PrP^{Sc} has less α -helical structure and a high β -sheet content. Comparisons of secondary structures of PrP^C and PrP^{Sc} were performed on proteins purified from Syrian hamster (SHa) brains.²⁸⁰ Limited proteolysis of PrP^{Sc} produces PrP 27–30, which retains prion infectivity; under these conditions, PrP^C is completely hydrolyzed (Fig. 76.1).

Using nuclear magnetic resonance (NMR) spectroscopy, solution structures of rec SHa and mouse (Mo) PrPs produced in bacteria showed three α -helices denoted A, B, and C as well as two short β -strands.^{223,324} These recPrPs are thought to have structures similar to those of PrP^C.¹⁶⁰ The atomic structure of PrP^{Sc} has not been determined because of the insolubility of the protein. Electron crystallographic and x-ray diffraction studies of PrP 27–30 have been used to constrain computational models of PrP^{Sc}, suggesting it contains α -helix C and a portion of α -helix B, whereas α -helix A, the two β -strands, and the surrounding segments form a β -helix.^{146,434} Fiber diffraction studies of PrP^{Sc} and PrP 27–30 support the model with a

TABLE 76.2 Glossary of Prion Terminology

Term	Description
Prion	A proteinaceous infectious particle that lacks nucleic acid and can self-propagate.
PrP ^{Sc}	Abnormal, pathogenic isoform of the prion protein that causes illness. This protein is the only identifiable macromolecule in purified preparations of prions causing the diseases listed in Table 76.1.
PrP ^C	Cellular isoform of the prion protein.
PrP 27–30	N-terminally truncated PrP ^{Sc} , generated by digestion with proteinase K.
PRNP	Human PrP gene located on chromosome 20.
Prnp	Mouse PrP gene located on syntenic chromosome 2. <i>Prnp</i> controls the length of the prion incubation time and is congruent with the incubation time genes <i>Sinc</i> and <i>Prn-i</i> . PrP-deficient (<i>Prnp</i> ^{0/0}) mice are resistant to prion infection.
PrP amyloid	Fibril of PrP fragments derived from PrP ^{Sc} by proteolysis. Plaques containing PrP amyloid are found in the brains of some mammals with prion disease.
Prion rod	An amyloid polymer composed of PrP 27–30 molecules. Created by detergent extraction and limited proteolysis of PrP ^{Sc} .
Protein X	A hypothetical macromolecule that is believed to act as a molecular chaperone in facilitating the conversion of PrP ^C into PrP ^{Sc} .

β -helix described earlier.⁴³¹ The authors of a recent investigation argue that PrP^{Sc}(Δ GPI) formed from anchorless PrP expressed in transgenic (Tg) mice is composed entirely of β -strands based on findings from H-D exchange studies.³⁶⁷

Electron crystallography of two-dimensional (2D) crystals suggest a trimeric arrangement of PrP 27–30 molecules within a unit cell, and ionizing radiation inactivation analyses have suggested that the infectious monomer is a trimer of PrP^{Sc} molecules.^{20,146} Other studies have shown that prion infectivity may exist in a wide variety of sizes, presumably due to the hydrophobic properties of PrP^{Sc}.³¹³ To date, it has not been possible to solubilize native, infectious PrP^{Sc} except by dissolving the prions into liposomes.¹¹⁸ Purified prion rods composed of PrP 27–30 were fragmented by sonication into spherical particles measuring 9 to 29 nm in diameter without any loss of infectivity.²⁴⁷ A more recent study showed that infectious prions particles measuring 17 to 27 nm in diameter and consisting of 14 to 28 PrP^{Sc} molecules could be obtained by partial disaggregation using the detergent Na *n*-undecyl SO₄.³⁶⁵

Recombinant antibody fragments have been used to map the surfaces of PrP^C and PrP^{Sc}, and those results are consistent with the foregoing structural data.²⁹² The structural transition from an α -helical-rich or unstructured protein into a β -sheet-rich molecule seems to be the fundamental event underlying the formation of nascent prions.

Limited proteolysis truncates the N-terminus of PrP^{Sc} to produce PrP 27–30 consisting of the C-terminal ~142 amino acids (Table 76.2) (Fig. 76.2). PrP 27–30 polymerizes into

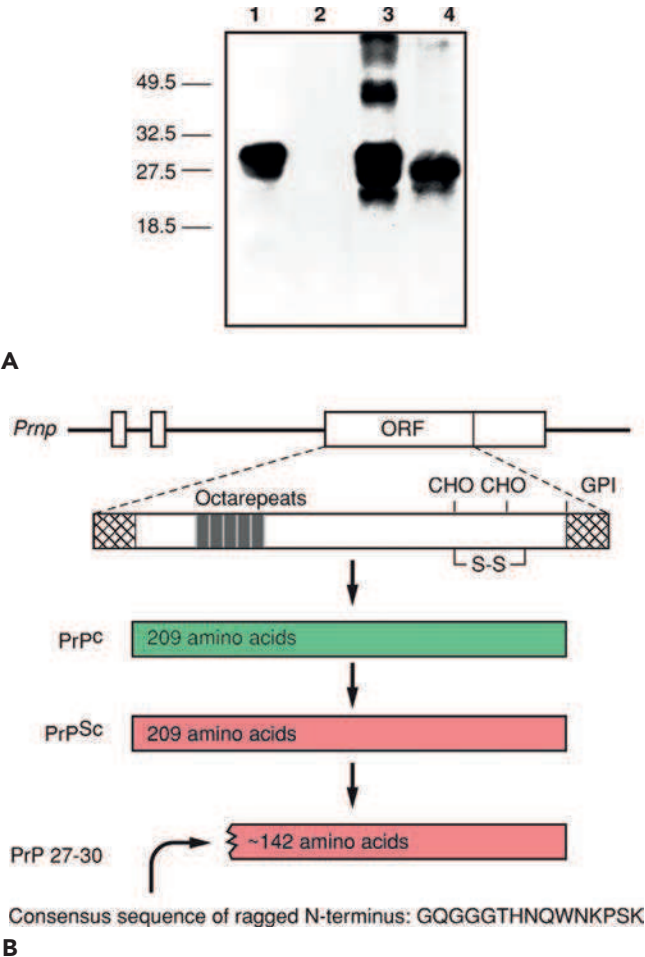

FIGURE 76.1. Prion protein isoforms. A: Western immunoblot of brain homogenates from uninfected (lanes 1 and 2) and prion-infected (lanes 3 and 4) Syrian hamsters. Samples in lanes 2 and 4 were digested with 50 $\mu\text{g mL}^{-1}$ of proteinase K for 30 minutes at 37°C. Cellular prion protein (PrP^C) in lanes 2 and 4 was completely hydrolyzed under these conditions, whereas approximately 67 amino acids were digested from the N-terminus of the disease-causing isoform (PrP^{Sc}) to generate PrP 27–30. After polyacrylamide gel electrophoresis (PAGE) and electrotransfer, the blot was developed with anti-SHaPrP R073 polyclonal rabbit antiserum.³⁵⁴ Molecular weight markers are depicted in kD. **B:** Diagram of the SHaPrP gene that encodes a protein of 254 amino acids. After processing of the N- and C-termini, both PrP^C and PrP^{Sc} consist of 209 residues. After limited proteolysis, the N-terminus of PrP^{Sc} is truncated to form PrP 27–30, which is composed of approximately 142 amino acids, the N-terminal sequence of which was determined by Edman degradation.

amyloid fibrils that are indistinguishable from fibrils found in amyloid plaques of the brains of mammals with prion disease.^{92,315} When full-length PrP^{Sc} was purified from SHa brain, only amorphous aggregates were seen by electron microscopy.²⁴⁸ Although limited digestion of purified PrP^{Sc} with proteinase K (PK) produced PrP 27–30, the ultrastructural appearance of the samples remained unchanged. Addition of a detergent, such as Sarkosyl, either before or after limited proteolysis, provoked the assembly of PrP 27–30 into rod-shaped structures with the ultrastructural and tinctorial properties of amyloid (Fig. 76.2).

FIGURE 76.2. Electron micrographs of negatively stained and immunogold-labeled Syrian hamster (SHa) prion rods. A: Prion rods recovered from sucrose gradients were negatively stained with 2% uranyl acetate. The prion rods are indistinguishable from many purified amyloids. **B:** Prion rods pretreated with 3 M urea and then immunostained with F4-31 mAbs derivatized with 10-nm gold particles. Bars in **A** and **B** represent 100 nm. **C:** Prion rods are composed of the SHaPrP 27–30 protein shown by sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE). **Left Panel:** gel stained with silver. **Right panel:** Western blot developed with polyclonal anti-PrP rabbit antiserum W5517.

It is important to realize that the formation of PrP amyloid is a nonobligatory feature of the PrP prion diseases. Only ~10% of all cases of sporadic CJD (sCJD) have detectable PrP amyloid deposits.⁹¹ In Tg mice expressing both MoPrP and SHaPrP, amyloid plaques were found in those Tg mice inoculated with Sc237 hamster prions but not in the Tg mice inoculated with RML mouse prions.³¹⁶ In studies of non-Tg mice, amyloid deposition was found to depend on the strain of scrapie prion.⁴²

PRIONS DIFFER FROM VIRUSES

Prions differ from viruses in many respects. In contrast to viruses that possess an RNA or DNA genome, prions are devoid of a nucleic acid genome that directs the synthesis of their progeny. Many investigators argued for a nucleic acid genome within the infectious prion particle, whereas others contended for a small, noncoding polynucleotide of either foreign or cellular origin. No nucleic acid has been found, despite intensive searches using a wide variety of techniques and approaches.³³⁶

Prions are composed entirely of protein. In mammals, the most well-studied prions are composed of PrP^{Sc}, which is formed from PrP^C expressed normally in all mammals studied to date. PrP is encoded by a chromosomal gene, designated *PRNP* in humans and *Prnp* in mice. The PrP gene is located on the short arm of chromosome 20 in humans and the syntenic region of chromosome 2 in mice.³⁷⁰ That prions are composed entirely of protein is supported by numerous studies. The most convincing of these studies are those describing the creation of prion infectivity by modifying the conformation of a synthetic or recombinant polypeptide. Such studies have been reported in both mammals and fungi; they are reviewed in detail below.

In contrast to viruses, prions are nonimmunogenic. Mammals fail to mount an immune response to PrP^{Sc}. The lack of an immune response presumably reflects the sharing of epitopes by PrP^C and PrP^{Sc},²⁹² as well as tolerance to PrP^C.³¹² Because viral proteins are encoded by the genome of a foreign pathogen, these proteins often elicit a profound immune response, which is the basis for vaccination.

When prions and viruses are passed from one host species to another, the consequences are quite different. The passage of prions from one host to another is accompanied by the acquisition of a new PrP amino acid sequence encoded by the genome of the new host. The crossing of prions from one species to another is restricted by what has been called the “species barrier”.²⁸⁵ Prion replication is more likely to occur when the evolutionary relationship is close between the newly infected animal and the host in which the prions last replicated.³⁴⁸ However, some strains of prions seem to be exceptions to this rule. For example, variant CJD (vCJD) prions from humans replicate much more readily in Tg mice expressing bovine (Bo) PrP than in Tg mice expressing human (Hu) or chimeric human-mouse PrP.^{14,204,352}

Although strains of viruses are encoded in nucleic acid genomes, no information resides in polynucleotides for prion strains. The issue of prion strains posed a profound conundrum for many years. How could an infectious pathogen composed only of protein encipher biological information? This riddle was solved when prion strains with different physical properties were isolated.^{25,401} Subsequently, new strains of prions have been isolated either by passage through mice expressing artificial PrP transgenes or by forming synthetic prions from recPrP produced in *Escherichia coli*.^{221,291}

The dramatically different principles that govern prion biology from those underpinning the viral diseases are frequently misunderstood. This lack of understanding has led to some regrettable decisions of great economic, political, and possibly public health importance. For example, scrapie and BSE have different names, yet they are the same disease in two different species. Scrapie and BSE differ in only two respects: (a) the PrP sequence in sheep differs from that of cattle at seven or eight positions of 270 amino acids,¹⁴² which results in different PrP^{Sc} molecules; and (b) most scrapie strains of prions seem to differ from BSE strains.

PRION DISEASE PARADIGM

Despite some similarities between prion and viral illnesses, these disorders are quite different. Viral diseases are infectious

illnesses and, as such, begin with infection by exogenous virions. In contrast, most prion diseases are initiated from within the host by a mechanism that causes prions to arise spontaneously. Often the term “prion infection” is used synonymously with “prion disease” because once prions form spontaneously, they can be transferred to another host and, thus, are infectious.

The prion diseases are uniformly fatal. No human or animal has ever recovered from a prion disease once neurologic dysfunction is manifest. No host defenses are mounted in response to prion infection: No humoral immunity, no cellular immunity, and no interferons are elicited to the replicating prion.

In humans, the PrP prion diseases occur in three different forms: (a) sporadic, (b) inherited, and (c) infectious (Table 76.1). In the sporadic and inherited forms of prion disease, prions arise spontaneously. Although the incidence of sporadic prion disease is low (one to five cases per 10⁶ people), this is the most common form of prion disease, accounting for approximately 90% of all cases. The inherited forms of prion disease account for ~10% of all cases of prion disease. In contrast, the infectious forms of human prion disease account for <1% of all cases. Whether the infectious forms of human prion disease are underestimated and whether low levels of animal prions in the food supply are responsible for 10% to 20% of the sporadic cases are unknown.

Molecular genetic studies have been crucial in deciphering the novel features of the prion disease paradigm. In the sporadic form of prion disease, the sequence of the PrP gene is wild-type (wt), whereas in the inherited prion diseases, the sequence of the PrP gene harbors a nonconservative substitution or insertion. As noted previously, both the sporadic and inherited prion diseases arise spontaneously. In contrast, the infectious prion diseases result from exposure to an exogenous source of prions. Generally, the PrP genes of humans and animals infected with exogenous prions are wt (i.e., these genes do not carry a mutation).

Before the discovery that mutations in the PrP gene cause familial prion disease, geographic clusters of prion disease were believed to be due to common-source exposures to exogenous prions. For example, Libyan Jews with a very high incidence of CJD were believed to have contracted the disease by eating lightly cooked sheep brain.⁶ Molecular genetic investigations showed that every Libyan Jew developing prion disease carried a PrP gene mutation, resulting in an E-to-K substitution at position 200 (Table 76.3).^{139,166} Risk analysis studies revealed that every Libyan Jew carrying the E200K mutation would eventually develop prion disease if he or she did not otherwise die of some other illness.

Investigations of humans with PrP gene mutations were extended to Tg mice. Tg mice expressing high levels of MoPrP(P101L), the analogous mutation causing Gerstmann-Sträussler-Scheinker (GSS) disease in humans, developed neurodegeneration spontaneously.⁴⁰⁰ Extracts prepared from the brains of these mice transmitted disease after approximately 250 days to other Tg mice (designated Tg196) expressing low levels of MoPrP(P101L). Subsequently, a synthetic PrP peptide of 55 residues carrying the P101L mutation, designated MoPrP(89–143,P101L), was produced and inoculated into the Tg196 mice.¹⁸⁶ The Tg196 mice developed CNS dysfunction about 1 year after inoculation, and brain extracts from the ill mice were found to produce disease on serial passage.^{268,405}

TABLE 76.3 Examples of Human PrP Gene Mutations Found in the Inherited Prion Diseases

Inherited prion disease	PrP gene mutation
Gerstmann-Sträussler-Scheinker disease	P102L ^a
Gerstmann-Sträussler-Scheinker disease	A117V
Familial Creutzfeldt-Jakob disease	D178N, V129
Fatal familial insomnia	D178N, M129 ^a
Gerstmann-Sträussler-Scheinker disease	F198S ^a
Familial Creutzfeldt-Jakob disease	E200K ^a
Gerstmann-Sträussler-Scheinker disease	Q217R
Familial Creutzfeldt-Jakob disease	Octarepeat insert ^a

^aSignifies genetic linkage between the mutation and the inherited prion disease.

The MoPrP(89–143,P101L) peptide produced disease in the Tg196 mice only if it was folded into a β -rich conformation.

An approach similar to the one used in the studies with the MoPrP(89–143,P101L) peptide was employed with wt PrP. In these studies, wt MoPrP(89–230) was produced in *E. coli*, purified by chromatography, and polymerized into amyloid fibrils.^{77,79,220} The amyloid fibrils were injected into Tg mice expressing MoPrP(89–230) and produced neurodegeneration after approximately 500 days. Brain extracts from the ill Tg mice contained protease-resistant PrP and produced disease on subsequent passage into both wt and Tg mice.²²¹ Several investigators have developed alternative approaches that have also generated prions *de novo*.^{93,231} Taken together, these studies demonstrated that only PrP^C is required to generate prion infectivity and, as such, spontaneous forms of prion disease can occur in any mammal because PrP^C seems to be ubiquitous among this class of vertebrates.

Spontaneous prion disease contrasts with viral disorders, where exogenous infection is required, except in the case of latent retroviral genomes. For example, after infection with exogenous HIV, the virus may disappear, but often its RNA genome has been reverse-transcribed into DNA, and the DNA copies may remain dormant for years.

MOLECULAR BIOLOGY OF PRION PROTEINS

PrP is encoded by a chromosomal gene denoted *Prnp*, which is a member of the *Prn* gene family. The second member of this family to be identified is the *Prnd* gene that lies approximately 19 kb downstream from the PrP locus and encodes the doppel (Dpl) protein.²⁶¹ The respective genes that encode PrP and Dpl appear to represent ancient gene duplication that occurred prior to the speciation of mammals. The sequences are approximately 25% identical, but the structures of the two proteins are highly conserved²⁶¹ (Fig. 76.3). In contrast to PrP, which is expressed in many different tissues, Dpl expression is confined to the testis. Both Dpl and PrP are found on the surface of sperm, but their functions are unknown. In contrast to PrP-deficient (*Prnp*^{0/0}) mice, Dpl-deficient (*Prnd*^{0/0}) mice are sterile. The knockout of both PrP and Dpl genes resulted in a sterile phenotype.²⁷⁸ A third member of the *Prn* gene family is *Sprn*, which encodes the Shadoo (Sho) protein. Sho shares some structural features with

FIGURE 76.3. Comparison of the nuclear magnetic resonance (NMR) structures of mouse doppel (Dpl) protein and prion protein (PrP). Backbone topology of mouse Dpl(26–157)²⁵⁹ and mouse PrP(121–231).³²⁴ (Figure prepared by Jane Dyson and Peter Wright.)

PrP and/or Dpl, such as a glycosylphosphatidyl inositol (GPI) anchor, an N-linked complex oligosaccharide, a central hydrophobic tract, and N-terminal amino acid repeats.^{303,418} Notably, the level of Sho was inversely proportional to the level of PrP^{Sc} in the brains of prion-infected mice.⁴¹⁷

In two *Prnp*^{0/0} lines, Purkinje cell loss was accompanied by ataxia beginning at approximately 70 weeks of age.³³⁸ Crossing one of these *Prnp*^{0/0} lines with Tg mice overexpressing MoPrP rescued the ataxic phenotype. This conundrum was solved with the discovery of Dpl; it became clear that Dpl expression in the brains of *Prnp*^{0/0} mice provoked cerebellar degeneration.²⁶¹ The expression of Dpl in the CNS was due to intergenic splicing of the nontranslated exons of the PrP gene with the translated exon of Dpl. That Dpl expression is neurotoxic was demonstrated by construction of Tg mice expressing Dpl in the brain.^{262,329}

The entire ORF of all known mammalian and avian PrP genes resides within a single exon, which eliminates the possibility that PrP^{Sc} arises from alternative RNA splicing. The two exons of the SHaPrP gene are separated by a 10-kb intron; exon 1 encodes a portion of the 5′ untranslated leader sequence. The PrP genes of Syrian hamster, mouse, sheep, and rat contain three exons, with exon 3 encoding the ORF and 3′ untranslated region. The promoters of both the SHaPrP and MoPrP genes contain multiple copies of G-C-rich repeats and are devoid of TATA boxes. These G-C nonamers represent a motif that may function as a canonic binding site for the transcription factor Sp1.

Expression of the PrP Gene

Although PrP messenger RNA (mRNA) is constitutively expressed in the brains of adult animals,^{68,274} it is highly regulated during development. In the septum, levels of PrP mRNA and choline acetyltransferase were found to increase in parallel during development. In other brain regions, PrP gene expression occurs at an earlier age. *In situ* hybridization studies show that the highest levels of PrP mRNA are found in neurons.²¹⁰

Although PrP^C is expressed in many tissues,²⁷⁴ only a few cell types appear to support PrP^{Sc} formation: neurons, myo-

cytes, follicular dendritic cells, and B lymphocytes.^{30,196,318} Whether astrocytes support PrP^{Sc} formation is debatable. Curiously, PrP^{Sc} formation appears to be elevated in lymphocytes, where an inflammatory response has been provoked.¹⁵⁵ That PrP^{Sc} formation occurs in a restricted set of cells, despite widespread expression of PrP^C, would seem to argue that auxiliary molecules (e.g., protein X) feature in prion replication.

On the Function of PrP^C

Although the function of PrP^C has eluded definition for many years, an enlarging body of evidence is accumulating that argues in favor of a role for PrP^C in signal transduction. Disruption of the PrP gene in mice results in animals with normal development, a normal lifespan, and no obvious abnormality.^{46,236} *Prnp*^{0/0} mice remain healthy for more than 2 years. Acute suppression of PrP expression by addition of doxycycline to the drinking water of bigenic mice with an inducible PrP transgene under the control of the tetracycline promoter did not result in any untoward effects in the adult mice.^{334,406} Similarly, bigenic mice, in which neuronal PrP expression was terminated in adulthood, showed no discernible deficits.²³⁴

In one study, *Prnp*^{0/0} mice were found to have abnormal sleep/wake cycles and altered circadian rhythms.⁴⁰⁴ Other investigators reported attenuation of long-term potentiation (LTP) and several altered electrophysiologic parameters of the hippocampus in *Prnp*^{0/0} mice. Another study described deficits in hippocampal-dependent spatial learning and LTP in the dentate gyrus.⁸⁷

One approach to elucidating the function of PrP^C has been to identify interacting molecules.³⁴⁴ PrP^C binds copper,^{161,379} and five octapeptide repeats are responsible for the coordination of bivalent copper ions. PrP^C interacts or associates with a number of proteins, including bacterial HSP-60; the 37-kD/67-kD laminin receptor³²²; laminin; the Grb2 protein, which is central in many signal transduction pathways²⁶⁵; the lipid raft protein caveolin-1; and the neuronal cell adhesion molecule (N-CAM).³⁴⁵ Although these studies identified molecules interacting with PrP^C, they did not clarify its function.

The association of PrP with N-CAM on the surface of mouse neurons was found to result in recruitment of N-CAM to lipid rafts and activation of the p59Fyn kinase.³⁴¹ In an earlier study, binding of anti-PrP antibodies to the surface of 1C11 neuronal cells resulted in (a) activation of p59Fyn kinase,²⁶⁵ (b) production of NADPH oxidase-dependent reactive oxygen species, and (c) phosphorylation of the MAP extracellular regulated kinases 1/2 (ERK1/2).³⁴⁶

A role for PrP^C in axon growth was proposed after increased expression of PrP^C was detected on the surface of elongating retinal axons in hamsters,³³⁹ and a PrP-Fc fusion protein was shown to bind strongly to the granule cell layer of mouse cerebellum, suggesting the presence of one or more PrP^C-interacting ligands in this region. In studies that did not distinguish axons and dendrites, exposure of neonatal mouse cerebellar or hippocampal neurons to a PrP-Fc fusion protein enhanced the total length of neurites by a factor of ~1.5.⁶⁶ In a more recent study, the effect of PrP-Fc on neurite outgrowth in cultures of mouse neurons has been suggested to be mediated through its binding to N-CAM.³⁴¹

When purified SHa or Mo recPrP in an α -helical-rich conformation was added to the media of cultured rat fetal hippocampal neurons,¹⁸⁵ overnight exposure resulted in (a) a 2-fold increase in neurons with a differentiated axon, (b) a 14-fold increase in neurons with differentiated dendrites, (c) a

5-fold increase in axon length, and (d) the formation of extensive neuronal circuitry. Formation of synaptic-like contacts was increased by a factor of five after exposure to recPrP for 7 days. Neither the N-terminal nor C-terminal domains of recPrP or of Dpl enhanced the polarization of neurons. Inhibitors of PKC and Src kinases, including p59Fyn, blocked the effect of recPrP on axon elongation, whereas inhibitors of phosphatidylinositol 3-kinase showed partial inhibition, suggesting that signaling cascades involving these kinases are candidates for transduction of recPrP-mediated signals. The foregoing results argue that full-length PrP^C functions as a “growth factor” involved in the development of neuronal polarity.^{185,265}

Consistent with the foregoing results on neuronal cells, studies of T-lymphocyte activation also argue that PrP^C functions in signal transduction. Addition of anti-PrP antibodies to cultured T lymphocytes produced capping where PrP^C bound the reggie-1 and reggie-2 proteins.³⁸¹ PrP^C in association with the reggie (or flotillin) proteins clusters with p59Fyn and other kinases in caps where elevated phosphorylation of ERK1/2 was found.

Overexpression of Wild-Type PrP Transgenes

Mice expressing the wt SHaPrP transgene were inoculated with SHa prions. The abbreviated incubation times exhibited by these Tg mice demonstrated abrogation of the species barrier.³⁴⁸ The length of the incubation time after inoculation with SHa prions was inversely proportional to the level of SHaPrP^C in the brains of Tg(SHaPrP) mice.³¹⁶

Bioassays of brain extracts from clinically ill Tg(SHaPrP) mice inoculated with SHa prions revealed that SHa prions, but not Mo prions, were produced. Conversely, inoculation of Tg(SHaPrP) mice with Mo prions led to the synthesis of only Mo prions.

PrP Gene Dosage Controls the Incubation Time

Incubation times have been used to isolate prion strains inoculated into sheep, goats, mice, and hamsters.⁹⁸ The *Sinc* gene is a major determinant of incubation periods in mice. Once molecular clones of *Prnp* became available, a study showed that the incubation time locus, designated *Prn-i*, was found to be either congruent with or closely linked to *Prnp*.⁵⁴

Although the amino acid substitutions in PrP that distinguish *Prnp*^a from *Prnp*^b mice argued for the congruency of *Prnp* and *Prn-i*, experiments with *Prnp*^a mice expressing *Prnp*^b transgenes demonstrated a “paradoxical” shortening of incubation times. From studies of congenic and Tg mice expressing different numbers of the *a* and *b* alleles of *Prnp*, these findings were discovered not to be paradoxical but to result from increased PrP gene dosage.⁵³ When the RML isolate was inoculated into congenic and Tg mice, increasing the number of copies of the *a* allele was found to be the major determinant in reducing the incubation time; however, increasing the number of copies of the *b* allele also reduced the incubation time, but not to the same extent as that seen with the *a* allele. Gene targeting studies established that the *Prnp* gene controls the incubation time and, as such, is congruent with both *Prn-i* and *Sinc*.²⁶⁰

PrP-Deficient Mice Resist Prion Infection

Prnp^{0/0} mice inoculated with prions resist infection.^{45,312} *Prnp*^{0/0} mice were sacrificed 5, 60, 120, and 315 days after inoculation with RML prions, and brain extracts were bioassayed in Swiss CD-1 mice. Except for residual infectivity from the inoculum

detected at 5 days, all bioassay mice remained healthy. Introduction of a foreign PrP gene into *Prnp*^{0/0} mice renders the mice susceptible to the corresponding foreign prions.^{45,312,351,402}

Because *Prnp*^{0/0} mice do not express PrP^C, we reasoned that they might more readily produce α -PrP antibodies. *Prnp*^{0/0} mice immunized with Mo or SHa prion rods produced α -PrP antisera that bound MoPrP, SHaPrP, and HuPrP.³¹² That *Prnp*^{0/0} mice readily produce α -PrP antibodies is consistent with the hypothesis that mice are tolerant to PrP^C, and that PrP^C and PrP^{Sc} share many epitopes.

Species Variations in the PrP Sequence

PrP is posttranslationally processed to remove a 22-amino acid, N-terminal signal peptide. The C-terminal 120 amino acids contain two conserved disulfide-bonded cysteines and a sequence that beckons addition of a GPI anchor. Twenty-three residues are removed during the addition of this GPI moiety, which anchors the protein to the cell membrane.³⁷³ Contributing to the mass of the protein are two Asn side chains linked to large oligosaccharides with multiple structures that have been shown to be complex and diverse.¹⁰⁶ Although many species variants of PrP have now been sequenced, only the chicken sequence has been found to differ greatly from the human sequence. The alignment of the translated sequences from more than 40 PrP genes shows a striking degree of conservation between the mammalian sequences and is suggestive of the retention of some important function through evolution (Fig. 76.4). Cross-species conservation of PrP sequences makes it difficult to draw conclusions about the functional importance of many of the individual residues in the protein.

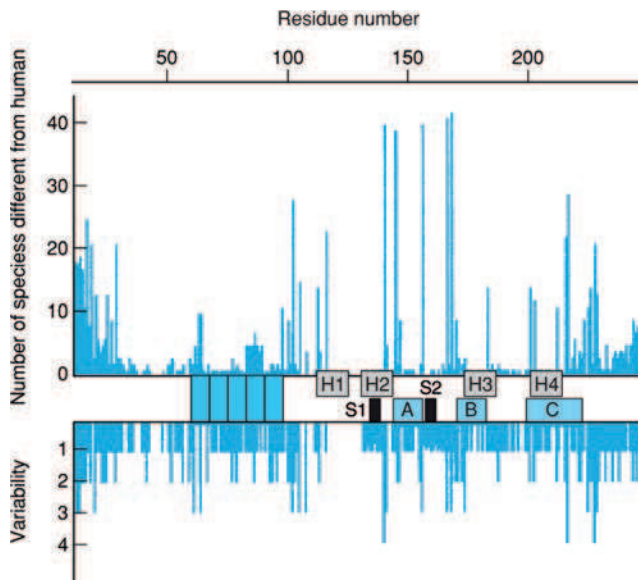

FIGURE 76.4. Species variations of PRNP. The x-axis represents the human prion protein (PrP) sequence with the five octarepeats and H1–H4 regions of putative secondary structure shown as well as the three α -helices A, B, and C and the two β -strands S1 and S2 as determined by nuclear magnetic resonance (NMR). Vertical bars above the axis indicate the number of species that differ from the human number of alternative amino acids at each position in the alignment. The vertical bars below the axis indicate variability for each PrP residue. (Data were compiled by Paul Bamorough and Fred E. Cohen.)

Notably, some investigators have found using low stringency analyses that zebrafish have candidate genes that encode proteins possessing many of the structural features of mammalian PrPs but relatively low sequence homology of ~20%.³²⁵ Two duplicated candidate piscine PrPs, designated PrP-1 and PrP-2, are expressed at high levels in the adult and developing brain. Knockdown of zebrafish PrP-1 prevented embryos from carrying out gastrulation and led to early developmental arrest. In contrast, PrP-2 depletion did not affect gastrulation but produced embryos with severely malformed heads and eyes. Remarkably, the PrP-1–arrested phenotype could be rescued not only by PrP-1, but also partially by PrP-2 and even mouse PrP mRNAs, strongly supporting the notion of functional homology between fish and mammalian PrPs.²³² PrPs have also been investigated from puffer fish and salmon.²³²

N-Terminal Sequence Repeats

The N-terminal domain of mammalian PrP contains five copies of a P(H/Q)GGG(G)WGQ octarepeat sequence, occasionally more, as in the case of one sequenced bovine allele, which has six copies. Although insertions of extra repeats have been found in patients with familial prion disease, naturally occurring deletions of single octarepeats do not appear to cause disease, and deletion of these repeats does not prevent PrP^C from undergoing a conformational transition to form PrP^{Sc}.^{110,386}

Using full-length recPrP, Cu²⁺ was found to bind with a much higher avidity than any other metal ion, but the concentration for half-maximal binding for Cu²⁺ was 14 μ M at pH 6.0, indicating a rather low affinity of PrP for Cu²⁺.³⁷⁹ At neutral pH, Cu²⁺–PrP complexes tended to form large aggregates and precipitate, so synthetic peptides containing the octarepeats were used to study the interaction of Cu²⁺ with PrP.¹⁶¹ When the PrP(58–91) peptide containing four octarepeats was studied, the binding of Cu²⁺ was found to be cooperative and highly pH dependent (Fig. 76.5). The midpoint of the pH dependence transition was pH 6.7, suggesting that the binding of Cu²⁺ occurred through the imidazole nitrogens of histidine residues. Because of these histidine residues, it was suggested that immobilized metal ion affinity chromatography (IMAC) might facilitate the purification of PrP^{Sc}; indeed, IMAC did prove to be useful in the purification of PrP^C.

In studies of full-length recPrP, Cu²⁺ was found to catalyze the oxidation of the histidine residues within the octarepeats. These findings argue that PrP may function as Cu²⁺-binding protein.³²¹ Interestingly, the copper-chelating reagent cuprizone administered to rodents causes spongiform degeneration resembling morphologically that induced by prions.²⁸⁶

STRUCTURES OF PRION PROTEIN ISOFORMS

When no chemical modifications differentiating PrP^C from PrP^{Sc} were found,³⁷⁴ the search for a conformational change that distinguishes the two PrP isoforms ensued. Fourier transform infrared (FTIR) and circular dichroism spectroscopy studies showed that PrP^C contains approximately 40% α -helix and little β -sheet, whereas PrP^{Sc} appeared to contain approximately 30% α -helix and 45% β -sheet.²⁸⁰ That the two PrP isoforms have the same amino acid sequence ran counter to the widely accepted view that the amino acid sequence specifies only one biologically active conformation of a protein.⁸ Like

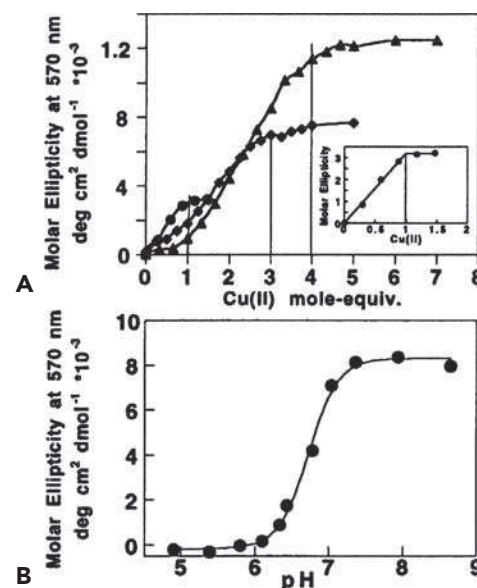

FIGURE 76.5. Binding of copper ions to synthetic peptides containing the octarepeats of the prion protein (PrP). **A:** Cu(II) binding curves: molar ellipticity at 570 nm with increasing amounts of Cu(II), pH 7.5. Filled circles, 2-His peptide, PrP(51–75) (0.34 mM). Filled diamonds, 3-His peptide, PrP(66–91) (0.021 mM). Filled triangles, 4-His peptide, PrP(58–91) (0.033 mM). **B:** pH dependence of the ellipticity at 570 nm for PrP(58–91). The pH dependence curve has been fitted to the following equation: $\Delta\epsilon_{\text{obs}} = [\Delta\epsilon_{\text{acid}}[H^+]^n + \Delta\epsilon_{\text{basal}}[H^+]Ka]/[H^+]^n + Ka$, in which n = Hill coefficient and Ka = acid dissociation constant for the transition. The midpoint of the transition is pH 6.7. (Reprinted from Viles JH, Cohen FE, Prusiner SB, et al. Copper binding to the prion protein: structural implications of four identical cooperative binding sites. *Proc Natl Acad Sci U S A* 1999;96:2042–2047, with permission; copyright © 1999 National Academy of Sciences, USA.)

PrP^{Sc}, PrP 27–30 has high β -sheet content,⁶³ which is consistent with the earlier finding that PrP 27–30 polymerizes into amyloid fibrils.³¹⁵ Recent H-D exchange experiments raise the possibility that PrP^{Sc} does not retain any α -helical structure³⁶⁷; the authors question the validity of earlier optical spectroscopy measurements.^{63,123,280}

Subcellular Localization of PrP^C and PrP^{Sc}

Prior to comparative studies on the structures of PrP^C and PrP^{Sc}, metabolic labeling studies showed that the acquisition of protease resistance in PrP^{Sc} is a posttranslational process.²⁹ In a search for chemical differences that would distinguish PrP^{Sc} from PrP^C, ethanolamine was identified in hydrolysates of PrP 27–30, which signaled the possibility that PrP might contain a GPI anchor.³⁷⁵ Both PrP isoforms were found to carry GPI anchors. PrP^C was found on the surface of cells, where it could be released by cleavage of the anchor. Subsequent studies showed that PrP^{Sc} formation occurs after PrP^C reaches the cell surface⁶¹ and localizes to caveolae-like domains (CLDs).^{144,396}

When PrP was directed to the cytoplasm of neurons in Tg mice, neurodegeneration was observed²²⁹; however, attempts to demonstrate the spontaneous formation of prion infectivity were unsuccessful. Although these Tg mice were initially heralded as a model for sCJD, their relevance remains unclear.

In other studies, the role of the GPI anchor that attaches PrP^C to the external surface of the plasma membrane³⁷⁵ was initially studied by expressing the mutant in scrapie-infected neuroblastoma (ScN2a) cells.³²⁶ In these scrapie-infected cells, anchorless PrP was converted into a protease-resistant molecule, arguing that it had acquired prion infectivity. In the brain, secreted forms of PrP^C lacking a GPI anchor are generated by sheddase cleavage of membrane-anchored PrP^C³⁹⁹; the physiological role of such unanchored PrP isoforms, termed PrP(Δ GPI), remains unclear. In earlier studies, Tg mice expressing low levels of PrP(Δ GPI) did not develop signs of spontaneous neurologic illness, but harbored large amyloidogenic PrP(Δ GPI) aggregates in the brain after exposure to prions.^{67,69} Mutations in human PrP leading to C-terminally truncated polypeptides lacking the GPI signal sequence, which cause the inherited prion disorder GSS, are known to result in the production of secreted, highly amyloidogenic forms of PrP.¹³¹ Other mutations that do not lead to truncated PrP but cause GSS, such as the F198S mutation, result in the production of anchorless PrP upon expression in cell culture.¹⁹¹ Importantly, GSS patients with mutations in PrP that result in the production of nearly full-length anchorless PrPs¹⁷⁶ suggest that anchorless PrP might be a cause of GSS-like neuropathology and clinical disease.

To investigate further the role of the GPI anchor in the biology of prions, several lines of Tg mice expressing various levels of PrP(Δ GPI) were established.³⁸⁰ The Tg mice expressing low levels of PrP(Δ GPI) remained healthy and exhibited little or no neuropathologic changes like those reported by others.⁶⁹ In contrast, neuronal expression of PrP(Δ GPI) at 1.7 \times levels compared to PrP^C expression in wt mice resulted in late-onset, spontaneous neurologic illness accompanied by a CNS amyloidosis resembling that found in GSS.³⁸⁰ This amyloidosis was transmissible to mice of the same line and to mice expressing wt GPI-anchored PrP^C. Mice expressing both PrP(Δ GPI) and wt PrP^C showed earlier onset of neurologic illness compared to those expressing only anchorless PrP. Neurologic illness was not hastened if Tg mice coexpressed PrP(Δ GPI) and N-terminally truncated PrP(Δ 23–88), arguing that the N-terminus has an important role in disease pathogenesis.³⁸⁰ These studies demonstrated that PrP(Δ GPI) spontaneously forms prions, and that membrane-bound wt PrP^C modulates the kinetics of PrP(Δ GPI) amyloid formation.

High-Resolution Structures of Recombinant PrP

Solution NMR structures of recSHaPrP(90–231), recSHaPrP(29–231), and recMoPrP(23–231) were determined after the proteins were expressed in *E. coli*, purified by gel filtration and reverse-phase chromatography, and refolded in α -helical-rich conformations similar to mammalian PrP^C (Fig. 76.6A). Circular dichroism measurements and ¹H-NMR spectra of bovine PrP^C were found to be consistent with results obtained with recombinant bovine PrP, arguing that the solution NMR structures are relevant for the structure of native PrP^C.¹⁶⁰ Most features of the structure of recSHaPrP (90–231) are similar to those reported earlier for the smaller recMoPrP(121–231) fragment.³²⁴ Like the shorter fragments, full-length PrP is also a three helix-bundle protein with two short antiparallel β -strands. Although the three helices form a globular C-terminal domain, the N-terminal domain is highly flexible and lacks identifiable secondary structure under the experimental condi-

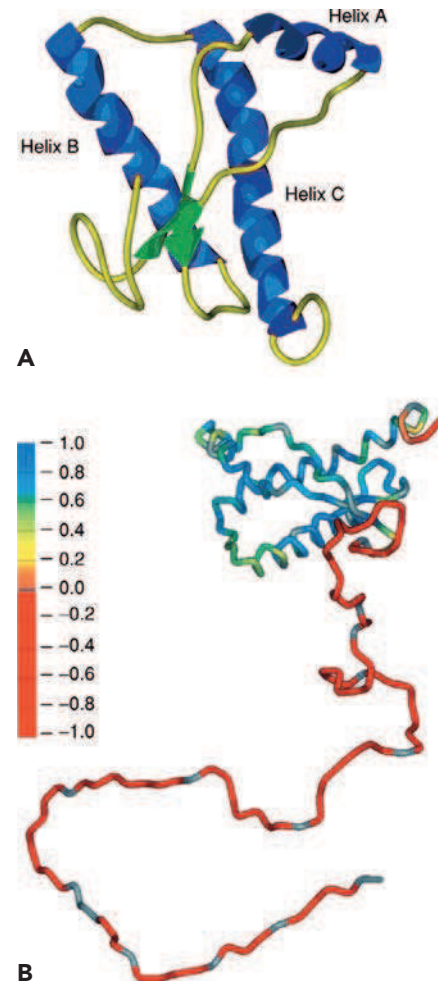

FIGURE 76.6. Structures of cellular prion protein (PrP^C). **A:** Nuclear magnetic resonance (NMR) structure of recSHaPrP(90–231). Presumably, the structure of the α -helical form of recSHaPrP(90–231) resembles that of PrP^C. recSHaPrP(90–231) is viewed from the interface where the disease-causing isoform (PrP^{Sc}) is believed to bind to PrP^C. α -Helix A, helix B, and helix C span residues 144–157, 172–193, and 200–227, respectively; residues 129–134 encompass strand S1 and residues 159–165 encompass strand S2. Residues 90 to 112 are not shown because marked conformational heterogeneity was found in this region, whereas residues 113 to 126 constitute the conserved hydrophobic region that also displays some structural plasticity.¹⁷⁵ **B:** Schematic diagram showing the flexibility of the polypeptide chain for PrP(29–231).¹⁰² The structure of the portion of the protein representing residues 90 to 231 was taken from the coordinates of PrP(90–231).¹⁷⁵ The remainder of the sequence was hand-built for illustration purposes only. The color scale corresponds to the heteronuclear [¹H]-¹⁵N NOE data: red for the lowest (most negative) values, where the polypeptide is most flexible, to blue for the highest (most positive) values in the most structured and rigid regions of the protein.¹⁰²

tions employed (Fig. 76.6B).¹⁰² Studies of recSHaPrP(29–231) indicate transient interactions between the C-terminal end of helix B and the highly flexible, N-terminal random coil containing the octarepeats (residues 29–125).¹⁰²

The solution NMR and x-ray structures of PrPs from 16 different species have been determined to be similar (Table 76.4). Moreover, the structures of MoDpl and HuDpl were

found to be similar to that of MoPrP and HuPrP, respectively, even though the two proteins share only 25% sequence similarity (Fig. 76.3).^{227,259} The folded domains of PrP and Dpl have a small but significant sequence homology (16–18% identity) to the N-terminal, extracellular domain of members of the Zrt- and Irt-like family (ZIPs) of zinc transporters.³⁴³ This homology may also extend to secondary and tertiary structural elements of PrP, Dpl, and the respective ZIPs. This sequence homology and potential structural similarity may indicate an ancestral relationship between the ZIP proteins and PrP and its paralogs.

Electron Crystallography of PrP^{Sc}

Because the insolubility of PrP^{Sc} has frustrated structural studies employing x-ray crystallography or NMR spectroscopy, electron crystallography was used to characterize the structure of two infectious variants of PrP. Isomorphous, 2D crystals of PrP 27–30 and a miniprion (PrP^{Sc}106) were identified by negative-stain electron microscopy.^{433,434} Image processing allowed the extraction of limited structural information to 10- to 15-Å resolution.⁴³² Comparing projection maps of PrP 27–30 and PrP^{Sc}106, the 36-residue internal deletion of the miniprion was visualized, and the N-linked sugars were localized (Fig. 76.7). The dimensions of the monomer, and the locations of the deleted segment and sugars, were used as constraints in the construction of models for PrP^{Sc}.¹⁴⁶

From a study of β -folds observed in globular proteins, it was determined that if PrP^{Sc} follows a known protein fold, it likely adopts a β -sandwich or parallel β -helical architecture.¹⁴⁶ With increasing evidence for a parallel β -sheet organization in amyloids,¹⁸⁴ it was argued that the sequence of PrP is compatible with a parallel left-handed β -helical fold. Left-handed β -helices readily form trimers, providing a natural template for a trimeric model of PrP^{Sc} (Fig. 76.8A). This trimeric model accommodates the PrP sequence from residues 89–175 in a β -helical conformation with the C-terminus (residues 176–227) retaining the disulfide-linked α -helical conformation observed in PrP^C. In addition, the proposed model matches the structural constraints of the 2D crystals, positioning residues 41–176 and the N-linked sugars appropriately. The parallel left-handed β -helical model provides a coherent framework that is consistent

with the stacking of trimeric units of PrP 27–30 to form PrP amyloid fibrils and predicts a height of four β -strands (= 19.2 Å) per molecule of PrP 27–30 (Fig. 76.8B).

X-Ray Fiber Diffraction of PrP 27–30 Amyloid

The specific interaction between PrP 27–30 and some polyoxometalates (POMs) favors formation of either PrP 27–30 amyloid fibrils or 2D crystals depending on the charge density of the POM (Fig. 76.9).⁴³⁴ Preparations enriched for PrP 27–30 amyloid fibrils were particularly suited for structural analyses by x-ray fiber diffraction.

Diffraction patterns of PrP 27–30 derived from the natural RML prion isolate or synthetic MoSP1 prion preparation both showed diffraction signatures on the meridian based on an axial repeat distance of 19.2 Å (Fig. 76.10). Although the first-order diffraction signal (at 19.2 Å) was not observed, the second-, third-, and fourth-order diffraction signals (at 9.6 Å, 6.4 Å, and 4.8 Å; white and black arrows) were present. Together, these reflections indicated that the repeating unit along the axis of the PrP 27–30 amyloid fibrils consists of four β -strands per molecule in a cross- β configuration. The equator of the diffraction patterns is characterized by a series of reflections originating from lipids and detergents. The absence of a strong equatorial diffraction signature around 10 Å indicates that the structure of PrP 27–30 amyloid is unlike that of “classical” amyloids that contain a stacked β -sheet architecture.⁴³¹ Instead, the meridional and equatorial reflections are most consistent with a β -helical architecture as was proposed in earlier modeling attempts (Fig. 76.8).

PRION REPLICATION

Many factors have been identified that influence the rate of prion formation. Although prion formation is inversely related to the length of the incubation time, it is directly proportional to the level of PrP^C expression in the brain and the amount of PrP^{Sc} in the inoculum. Another factor governing prion formation is the PrP sequence: Prion replication is generally facilitated when the sequences of PrP^C and PrP^{Sc} are identical. The strain-

(Figure prepared by Cédric Govaerts.)

specific conformation of PrP^{Sc} is also a major determinant influencing the rate of prion formation. Some prion strains exhibit short incubation times, whereas others produce prolonged incubation periods. Some of these findings presumably reflect the stability of the PrP^{Sc} , the targeting of PrP^{Sc} to replication-competent cells, and the rate of PrP^{Sc} clearance.

Once infection in a cell is initiated and PrP^{Sc} production begins, the mechanism of prion propagation remains uncertain. If the assembly of PrP^{Sc} into a specific trimeric arrangement is slow, then a nucleation-polymerization (NP) formalism may be relevant.¹⁷⁷ In NP processes, nucleation is the rate-limiting step, whereas elongation, or polymerization, is facile.

These conditions are frequently observed in peptide models of aggregation⁵⁸; however, studies with ScN2a cells and Tg mice expressing foreign PrP genes suggest that prion propagation occurs through a different process.

Although the NP reaction has gained support from yeast prion studies, few data exist to argue in favor of such a mechanism for mammalian prions. Moreover, the chaperone Hsp104 has been shown to play an important role in the replication of the Sup35 yeast prions by fragmenting amyloid fibrils and thereby making more seeds available.³⁶⁰ It is noteworthy that yeast prions do not infect cells but rather are transmitted horizontally from cell to cell by cytoplasmic mixing during

FIGURE 76.9. Inverse correlation between the quantities of prion rods and two-dimensional (2D) crystals in preparations with different polyoxometalates (POMs). **A:** With increasing charge density of Keggin-type POMs, the amount of prion rods decreased (dashed-line curve) as the amount of 2D crystals increased (solid curve), as determined by quantitative electron microscopy. The reductions in fibril content from phosphotungstic acid (PTA) to borotungstic acid (BTA) (factor ~2.9) and to metatungstate (HTA, $[\text{H}_2\text{W}_{12}\text{O}_{40}]^{6-}$) (factor ~3.9) were statistically significant, with $P = 0.015$ (*) and $P = 0.002$ (**), respectively. The correlation coefficient (r) for all four POMs is -0.97 (dotted line). The increases in 2D crystal content from PTA to BTA (factor ~4.0) and to HTA (factor ~4.3) were statistically significant, with $P = 0.009$ (*) and $P = 0.001$ (**), respectively. For all four POMs, $r = 0.93$. Because different methods of quantification were used for the prion rods and 2D crystals, different scales are shown. The error bars represent standard errors of the mean (SEMs). **B:** The negative charge of the Keggin-type POMs and the amount of precipitated PrP 27–30, as determined by conformation-dependent immunoassay (CDI), are not correlated ($r = -0.01$, dashed line). The error bars show the standard deviation. (Reprinted from Wille H, Shanmugam M, Murugesu M, et al. Surface charge of polyoxometalates modulates polymerization of the scrapie prion protein. *Proc Natl Acad Sci USA*. 2009;106:3740–3745, with permission; copyright © 2009 National Academy of Sciences, USA.)

White arrows indicate second and third orders of meridional 19.2-Å diffraction. **A:** The RML prion strain passaged in FVB mice and derived from the Chandler isolate. MoPrP 27–30 was purified by Sarkosyl extraction followed by PTA precipitation.⁴³⁴ Inset uses a different grayscale in order to show the weak, broad 4.8-Å diffraction. **B:** The MoSP1 synthetic prion strain derived from recPrP(89–230) amyloid, passaged twice through Tg9949 mice and purified as in A.

ming.⁴²⁷ Yeast prions are also transferred from one cell to another by cytoplasmic mixing without transfer of nuclear material; this process is called cytoduction.

On the Mechanism of Prion Propagation

Studies of Tg mice expressing both Mo and SHa PrP^C demonstrated that the infecting prion interacts with the corresponding PrP^C to produce Mo or SHa prions.³¹⁶ These findings argued that PrP^{Sc} acts as a template and binds to the species-specific substrate PrP^C. The concept that PrP^{Sc} acts as a template in prion replication was extended when different prion strains were found to possess distinct conformations of PrP^{Sc}.^{25,221,291,401}

Results from many lines of investigation argue that auxiliary macromolecules feature in the formation of nascent PrP^{Sc} (Table 76.5), although some investigators continue to argue that prion replication occurs without any non-PrP factors. The

possibility that auxiliary proteins play a role in the multiplication of prions was first entertained when MoPrP^C was found to inhibit the formation of HuPrP^{Sc} in Tg mice expressing HuPrP^C (Table 76.6).⁴⁰² The inhibition of Hu prion replication by MoPrP^C was relieved by disruption of the MoPrP gene or by expression of a chimeric Mo-Hu PrP transgene, designated MHu2M. These findings, combined with those from cultured cell experiments, suggest that an auxiliary macromolecule, designated protein X, binds to PrP^C prior to the binding of PrP^{Sc}.¹⁸⁷

Mutagenesis studies showed that reversion of some human residues in the chimeric transgene of Tg(MHu2M) mice resulted in shorter incubation times after inoculation with human CJD prions. Although the incubation time for CJD prions in Tg(MHu2M)5378 mice was ~191 d, it was reduced almost 50% to ~106 d in Tg(MHu2M,M165V,E167Q)22372

TABLE 76.5 Some Arguments for Auxiliary Molecules Participating in Mammalian Prion Replication

1. PrP^{Sc} formation is restricted to a few cell types such as neurons, corneas, myocytes, and follicular dendritic cells (FDCs); yet, PrP^C expression is widespread.
2. Only a few cultured cell lines expressing PrP are permissive to prion infection, demonstrating that PrP expression is necessary but not sufficient for prion replication.
3. PrP^{Sc} formation is restricted to cholesterol-rich microdomains called rafts; PrP^{Sc} formation is prevented by cholesterol depletion.
4. Mouse PrP^C inhibited conversion of human PrP^C into human PrP^{Sc} but did not retard chimeric human-mouse PrP^C from being converted into chimeric PrP^{Sc} in mouse brain.
5. Reversion of 3 of 9 human residues to mouse in chimeric PrP^C reduced the incubation times progressively for human prions.
6. Substitution of a basic amino acid at any of 4 positions in the C-terminal mouse region of chimeric human-mouse PrP^C rendered PrP ineligible for conversion into PrP^{Sc}. Any of these basic substitutions made PrP act as a dominant negative.
7. Prion replication faithfully copied the conformation of the infecting PrP^{Sc} template. To copy different prion strains demands that the replication process possesses a mechanism to maintain the fidelity of prion reproduction.
8. Mammalian organ homogenates facilitated PrP^{Sc} formation by pulsed sonication, whereas those from flies, fungi, and bacteria did not.

TABLE 76.6 Selective Reversion of Human Residues to Mouse in Chimeric PrP Shortens the Incubation Time for CJD Prions^a

Transgene	MoPrP genotype	Incubation time (mean days \pm SEM) (n/n_0)
Non-Tg FVB	+/+	701 (1/10)
HuPrP(V129)	+/+	721 (1/10)
HuPrP(V129)	-/-	263 \pm 2 (6/6)
MHu2M	+/+	238 \pm 3 (8/8)
MHu2M	-/-	191 \pm 3 (10/10)
MHu2M(M165V,E167Q)	-/-	106 \pm 2 (13/13)
MHu2M(M111V,M165V,E167Q)	-/-	79 \pm 2 (15/15)

^aInocula from sCJD(MM1) case designated RG. All MHu2M transgenes encode M129. n , number of sick mice; n_0 , number of inoculated mice.

mice by reverting residues 165 and 167 from human to mouse in the chimeric transgene (Table 76.6).^{204,402} A further reduction of greater than 30% in the incubation time to ~77 d was accomplished by reverting one additional human residue at position 111 in Tg(MHu2M,M111V,M165V,E167Q)1014 mice.¹³⁴ These findings argue for a mouse-specific factor that participates in prion replication: when residues 111, 165, and 167 are mouse, the incubation time for RML prions is reduced more than 60% from 200 to 75 d. The results are consistent with the proposal that PrP^C interacts both with PrP^{Sc} and an auxiliary factor, for example, protein X, which would explain why replication of chimeric Hu/Mo prions is facilitated by replacement of some human residues with mouse. Obviously, some human residues are required in chimeric PrP^C so as to initiate efficiently the formation of nascent chimeric MHu2M(M111V,M165V,E167Q) PrP^{Sc}. It seems difficult to explain the foregoing findings solely on the basis of enhanced interactions between the chimeric PrP isoforms; these observations also make it difficult to argue against a mouse-specific, non-PrP factor such as a chaperone participating in prion replication.

Additional evidence for protein X emerged as it began to be appreciated that PrP^C is expressed in many tissues, but PrP^{Sc} appears to be limited to neurons, myocytes, and follicular dendritic cells (Table 76.5).^{30,155,196} The tissue-specific formation of prions contends that another protein with highly restricted expression participates in PrP^{Sc} formation. Moreover, only a few cultured cell lines expressing PrP have proven to be permissive to prion infection, demonstrating that PrP expression is necessary but not sufficient for prion replication.¹³⁵ This argument was extended by studies with mutant PrP that is ineligible for GPI addition.^{69,326} That anchorless PrP^{Sc} is formed more slowly than wt PrP^{Sc} in mouse brains⁶⁹ contends that PrP^{Sc} formation is confined to a particular subcellular compartment. Earlier studies showed that the GPI anchor directs PrP^C to cholesterol-rich rafts where it comes in contact with PrP^{Sc}^{144,396} and, likely, auxiliary macromolecules. If prion replication occurs without the aid of auxiliary proteins, then we would expect that altering the subcellular localization of PrP^C would not diminish prion replication.

Site-directed mutagenesis studies identified four residues in the C-terminal region of PrP^C that play a critical role in PrP^{Sc} formation. Substitution of a Lys or Arg at any of these residues rendered mutant PrP^C ineligible for conversion into PrP^{Sc}.¹⁸⁷ When mutant PrP was coexpressed with wt PrP, mutant PrP acted as a dominant negative, preventing the conversion of wt PrP^C into wt PrP^{Sc}.¹⁸⁷ The mechanism of dominant-negative inhibition was hypothesized to be the binding of mutant PrP^C to protein X, which prevents wt PrP^C from binding and, thus, being converted into wt PrP^{Sc} (Table 76.5). The findings in cultured cells were subsequently reproduced in Tg mice expressing either mutant PrP^C as well as both wt and mutant PrP^C.²⁹⁴

In vitro studies using pulsed sonication described below were used to search for protein X, also called factor X. Employing purified PrP^C and PrP^{Sc}, homogenates prepared from many different organs of diverse mammalian species facilitated the formation of protease-resistant PrP.¹ Subcellular fractionation showed that the non-PrP protein X was found predominantly located in the lipid raft fraction, the site of PrP^{Sc} formation.^{29,61,396} Importantly, no protein X activity was found in homogenates prepared from lower organisms including yeast, bacteria and flies.

In studies of prion strain interference, Dickinson and colleagues argued that a nonscrape agent factor governs the rate of multiplication.⁹⁷ To explain the prolongation of the incubation time for 22A strain in VM mice by prior inoculation with the 22C strain, they hypothesized that a limited number of “replication sites,” that is, factor X’s, existed. In other words, the affinity of the 22C prion strain for the replication sites was higher than that of 22A and thus, 22A replication was inhibited because 22A was unable to displace 22C from these sites. Recently, competition between the DY and HY strains of prions was studied by inoculating the prions into the sciatic nerve of Syrian hamsters.³⁵⁸ The investigators suggested that DY PrP^{Sc} prevented multiplication of HY PrP^{Sc} by sequestering either SHaPrP^C or occupying the prion “replication sites.”

***In vitro* Production of PrP^{Sc}**

Initial reports of the cell-free production of PrP^{Sc}-like molecules involved incubating an excess of PrP^{Sc} with PrP^C and measuring increases in protease-resistant PrP levels.⁶² The small increase in protease-resistant PrP derived from PrP^C did not permit meaningful measurements of prion infectivity. A modified system was used to investigate the need for non-PrP proteins in the suspension: after 48 h of incubation with a 10-fold molar excess of PrP^{Sc}, PrP^C acquired protease-resistance resembling PrP^{Sc}.³³² After partial purification of 139A or Me7 prions, the PrP^{Sc} was mixed with chimeric mouse-hamster (MHM2) PrP^C that was expressed in CHO cells. The formation of PrP^{Sc} was prion strain-specific based on the migration of PrP^{Sc} on Western blots. Although no formation of nascent PrP^{Sc} was observed under the same conditions using purified proteins without cell lysate, conversion was restored when PrP^C-depleted cell lysate was added to the purified proteins. The authors argue that these findings provide evidence for the participation of chaperone-like activity in the formation of PrP^{Sc}.

To increase the *in vitro* conversion of PrP^C to PrP^{Sc}, mixtures of brain homogenates from normal and prion-infected rodents were sonicated.³³¹ Repeated brief pulses of sonication were employed with 30- to 60-min intervals between them to prevent overheating; the procedure has been dubbed “protein

misfolding cyclic amplification,” or PMCA. Notably, PMCA has been found to produce prion infectivity in brain homogenates obtained from uninfected animals; this finding limits the value of PMCA as a diagnostic test for prion disease.^{18,93,96,413}

When PMCA was introduced, brain homogenate from prion-infected Syrian hamsters (SHa) were diluted 500-fold into brain homogenate from uninfected hamsters.³³¹ Subsequent studies employed purified PrP^C as substrate as well as purified PrP^{Sc} as the seeding template. PMCA was found to be sensitive to the PrP sequence as well as the source of homogenate^{55,56,271}; in addition, the extent of PrP^C glycosylation was found to influence amplification of PrP^{Sc}.²⁷² Cofactors such as lipids and polyanions like RNAs have also been found to modify the amplification of PrP^{Sc}.^{94,414}

Despite numerous studies extolling the virtues of PMCA, some caveats should be noted. PMCA results in uneven amplification of prions—from well to well and from experiment to experiment—which produces great variability²⁹⁸ and prevents the resulting data from being quantified. It is well documented that sonication produces an uneven distribution of energy, resulting in cavitation and high temperatures associated with cavitation¹¹¹ as well as the generation of free radicals.²³⁸ Protein conformation is sensitive to temperature denaturation, and free radicals may covalently alter proteins. Both cavitation and free-radical modification of proteins are stochastic processes and inherently difficult to control, potentially explaining the variability observed in PMCA experiments. In contrast, the denaturing agents urea and guanidine, used in the production of synthetic prions described below,^{77,79,220} result in comparatively even and well-defined denaturation of protein throughout the solution. In some cases, sonication initiates amyloid formation with proteins that are usually monomeric,³⁷⁶ indicating denaturation. In those studies, six different purified proteins showed increased aggregation and amyloid formation as a function of sonication time. Furthermore, such alterations in protein conformation may result in the degradation of the protein.⁴⁴¹ Degradation and denaturation may thus limit the usefulness of products produced by PMCA for structural studies.

That pulsed sonication promotes amyloid formation and the spontaneous formation of prion infectivity is consistent with other studies showing that both fungal and mammalian prion infectivity can be generated by polymerization of prion proteins into amyloids. In Tg mice, a 55-mer peptide carrying the P101L mutation was rendered infectious by increasing the β -structure^{186,405}; also, recPrP of wt sequence was rendered infectious by polymerization into amyloid fibrils.^{77,220} Similar results were obtained when the prion domain of the Sup35 yeast protein and the HET-s protein of the filamentous fungus *Podospora anserina* were polymerized into amyloid.^{230,371} More recently, altering the conditions of amyloid polymerization has been shown to produce different strains of both fungal and mammalian prions.^{77,195,395}

Prion Formation and Clearance

The accumulation of prions occurs when the rate of formation exceeds the rate of clearance. Bigenic mice were inoculated with RML prions and, after 56 days, they were given oral doxycycline, which suppressed PrP^C synthesis by approximately 95%. Under these conditions, the levels of PrP^{Sc} in the brains of bigenic mice were determined as a function of time.³³⁴ Such measurements allow calculation of the half-life ($t_{1/2}$) values of 1.5

days for both protease-sensitive and protease-resistant PrP^{Sc}. In contrast, a $t_{1/2}$ value of 18 hours was determined for PrP^C. In ScN2a cells, the $t_{1/2}$ value for PrP^C was 2.6 to 7 hours, while the $t_{1/2}$ for protease-resistant PrP^{Sc} was 30 hours.^{29,60}

Dominant-Negative Inhibition

As noted above, the discovery of dominant-negative inhibition of PrP^{Sc} gave additional support to the argument that an auxiliary protein participates in prion replication (Table 76.5). Substitution of a Hu residue at position 214 or 218 in MHM2 PrP prevented formation of MHM2 PrP^{Sc}.¹⁸⁷ The side chains of residues 214 and 218 protrude from the same surface of the C-terminal α -helix, forming a discontinuous epitope with residues 167 and 171 in an adjacent loop. When MHM2 PrP and MHM2 PrP(Q218K) were co-expressed, the conversion of MHM2 PrP^C into PrP^{Sc} was inhibited, arguing that MHM2 PrP(Q218K) was acting as a dominant negative. Like MHM2 PrP(Q218K), substitution of a basic residue at position 167 or 171 prevented PrP^{Sc} formation. Similar results were obtained when studies were performed with cells expressing MHM2 PrP(Q167R). Notably, the E219K substitution seems to render humans resistant to sCJD and Q171R renders sheep resistant to scrapie (Fig. 76.11).

Tg(MoPrP;Q167R)*Prnp*^{0/0} mice expressing mutant PrP at levels equal to non-Tg FVB mice were inoculated with prions and remained healthy for more than 550 days; immunoblots of brain homogenates and histologic analysis revealed no detectable protease-resistant PrP^{Sc}.²⁹⁴ Tg(MoPrP;Q167R)*Prnp*^{+/+} mice expressing both mutant and wt PrP exhibited neurologic dysfunction at ~450 days after inoculation; the brains of three of these mice that were sacrificed at 300 days revealed low levels of PrP^{Sc}, as well as numerous vacuoles and severe astrocytic gliosis.

In addition to studies with Tg(MoPrP;Q167R)*Prnp*^{+/+} mice, Tg(MoPrP;Q218K)*Prnp*^{+/+} mice demonstrate that PrP^{Sc} formation occurred slowly when dominant-negative and wt PrP are coexpressed. Expression of MoPrP(Q167R) at 1× or MoPrP(Q218K) at 16× in the absence of wt MoPrP failed to support replication of RML prions in these mice. Whether either of these dominant-negative PrPs in mice can support replication of another strain of prions such as 301V is unknown. The 301V strain was isolated from a case of BSE,¹¹⁴ and BSE prions are known to replicate in sheep expressing OvPrP(Q171R), in which ovine Q171R is equivalent to mouse Q167R.¹⁶³

DIAGNOSIS OF PRION DISEASES

The clinical diagnosis of human prion disease is often difficult until the patient shows profound signs of neurologic dysfunction.⁴²⁹ In humans with sCJD, the most common clinical presentation is a progressive dementia. Approximately 10% of sCJD patients present with a progressive ataxia.

It is widely accepted that the clinical diagnosis is provisional until a tissue diagnosis either confirms or rules out the clinical assessment. Prior to the availability of antibodies to PrP, a tissue diagnosis was generally made by histologic evaluation of neuropil vacuolation. Immunohistochemistry (IHC) using anti-GFAP antibodies in combination with hematoxylin-and-eosin staining preceded the use of anti-PrP antibody staining.

FIGURE 76.11. Mutations and polymorphisms of the prion protein gene. Above the line of the human sequence are mutations that cause inherited prion disease. Polymorphisms, some but not all of which are known to influence both the onset and the phenotype of disease, in the PrP genes of human, mouse, sheep, elk, and cattle are shown in green. Residue numbers in parentheses correspond to the human codons.

Postmortem Tissue Diagnosis of Prions

A study of the brains from eight clinically affected goats inoculated with the SSBP1 prion isolate challenged the accuracy of IHC.¹¹³ Thalamic samples taken from seven of eight goats with scrapie were positive for PrP^{Sc} by western blotting but negative by IHC. The eighth goat was negative by both western blotting and IHC. Consistent with these findings in goats, results of a study of humans who died of sCJD or familial CJD (fCJD) showed that IHC of formalin-fixed, paraffin-embedded human brain samples was substantially less sensitive than the conformation-dependent immunoassay (CDI).³³⁵

Concerned that limited PK digestion was hydrolyzing some or even most PrP^{Sc} in samples, the CDI was developed so as to not require PK digestion. The CDI revealed that as much as 95% of PrP^{Sc} is protease sensitive (sPrP^{Sc}), and thus, it was being destroyed during the limited proteolytic digestion used to hydrolyze PrP^C. Protease-sensitive PrP^{Sc} comprises 80% to 95% of the total PrP^{Sc} in the frontal lobes and in the white matter in CJD cases (Fig. 76.12).³³⁵

The CDI detected HuPrP^{Sc} with a sensitivity comparable to the bioassay for prion infectivity in Tg(MHu2M) mice (Fig. 76.13). The high sensitivity achieved by the CDI is due to several factors, including the use of phosphotungstic acid (PTA) that specifically precipitates sPrP^{Sc} and rPrP^{Sc}^{217,335} (Table 76.7). PTA has also been employed to increase the sen-

sitivity of western blots, enabling the detection of rPrP^{Sc} in human muscle and other peripheral tissues.^{136,412} A comparison between the CDI and western blotting on brain samples from sCJD and vCJD patients showed that the CDI was 50- to 100-fold more sensitive.²⁵⁷ In a recent study described below, a highly sensitive sandwich enzyme-linked immunosorbent assay (ELISA) using a bioluminescence detection system was reported.¹⁰³

The CDI detected PrP^{Sc} in all regions of the brain that were examined in 24 sCJD and 3 fCJD(E200K) cases. Comparative analyses demonstrated that the CDI was superior to both histology and IHC. When 18 regions of 8 sCJD and 2 fCJD(E200K) brains were compared, it was discovered that both histology and IHC were unreliable diagnostic tools, except for samples from a few brain regions. In contrast, the CDI was a superb diagnostic procedure because it detected PrP^{Sc} in all 18 regions in 8 of 8 sCJD and 2 of 2 fCJD(E200K) cases.³³⁵

The CDI was also used to study GSS caused by the P102L mutation. In mice expressing the analogous mutant PrP transgene causing GSS in humans, the CDI detected high levels of sPrP^{Sc}(P101L) and low levels of rPrP^{Sc}(P101L) long before neurodegeneration and clinical symptoms were present.⁴⁰⁵ sPrP^{Sc}(P101L) and low concentrations of rPrP^{Sc}(P101L) previously escaped detection.

FIGURE 76.12. The most abundant disease-causing isoform (PrP^{Sc}) in the frontal cortex and white matter of sporadic Creutzfeldt-Jakob disease (sCJD) brains is protease-sensitive (blue bars, calculated from measurements of total PrP^{Sc} [white bars] and rPrP^{Sc} [gray bars]). Before measurement by the conformation-dependent immunoassay (CDI), undigested samples were phosphotungstic acid (PTA)-precipitated to measure total PrP^{Sc} or digested with 50 μ g per mL proteinase K at 37°C for 1 hour, followed by PTA precipitation to determine rPrP^{Sc}.³³³ The graphs show mean values \pm standard error of the mean (SEM) obtained from duplicate measurements of samples from the frontal cortex ($n = 19$) and white matter ($n = 12$) of sCJD-infected brains. (Reprinted from Safar JG, Geschwind MD, Deering C, et al. Diagnosis of human prion disease. *Proc Natl Acad Sci U S A* 2005;102:3501–3506, with permission; copyright © 2005 National Academy of Sciences, USA.)

Antemortem Diagnosis

Except for brain biopsy, no reliable antemortem test exists for prion disease. Although a variety of preliminary reports have described surrogate markers or PrP^{Sc} in blood, none of these markers has been developed into a reliable antemortem test.^{39,107} For example, the mRNA transcript of erythroid differentiation-related factor (EDRF) was reported to be diminished in the spleens of terminally ill mice inoculated with

scrapie prions.²⁵³ Attempts to show that EDRF is depressed in the blood of mice with scrapie or humans with CJD have been disappointing.

The stress protein 14-3-3 has been studied in the cerebrospinal fluid (CSF) of patients with CJD. Although some studies report that most sCJD patients show elevated levels of 14-3-3, other reports describe elevations in only ~50% of patients.¹²⁵ Patients with vCJD generally show no change in 14-3-3 levels in the CSF.⁴²⁹ Elevations in 14-3-3 CSF levels are nonspecific and have been found in stroke, herpes encephalitis, and several other neurologic disorders.

The detection of protease-resistant PrP in the urine of hamsters, cattle, and humans with prion disease was greeted with enthusiasm³⁵⁷; however, subsequent studies showed that the presumed immunostaining for PrP was an artifact.³⁵³ Immunoglobulin light chains or fragments of heavy chains were found to be detected by the secondary antibody used in the immunoassays.

A chemiluminescent capture assay for PrP^{Sc} in blood of humans with CJD was developed using a capture ELISA, where the detection was performed with the biotinylated primary mAb ICSM18. The amount of PrP^{Sc} bound to a solid phase was measured using NeutrAvidin-HRP that hydrolyzed a chemiluminescent substrate. Fifteen of 21 vCJD blood samples were positive using this assay, whereas 100 normal controls, 16 patients with probable sCJD, 11 patients with definite sCJD, and 42 patients from other neurodegenerative diseases (including 31 with Alzheimer's disease and 4 with frontotemporal dementia) were all negative.¹⁰³

Bovine Spongiform Encephalopathy Testing

In March 1996, 11 British teenagers and young adults were described to have died of a new form of prion disease, later labeled vCJD. In these young patients, the patterns of PrP^{Sc} deposition in the brain were markedly different from that found in typical CJD patients.^{90,429} The recognition that patients with vCJD were infected with BSE prions from cattle^{43,81,351} prompted the European Union to institute testing of all cattle older than 30 months of age at the time of slaughter. Currently, both western blotting and ELISA tests for rPrP^{Sc} are being used on brainstems from cattle. The CDI test, which measures both sPrP^{Sc} and rPrP^{Sc}, adapted to bovine brainstem has not been used routinely for testing cattle.

TABLE 76.7 Specificity of PrP^{Sc} Precipitation by NaMg PTA

Brain tissue ^a	n	CDI value	5% brain homogenate (cpm)	PTA pellet (cpm)	Fraction of PrP precipitated (%)
Uninoculated SHa	7	D	18,652 \pm 3,275	1,200 \pm 249	6.8 \pm 3.0
SHa inoculated with Sc237 prions	7	D	173,386 \pm 19,830	128,075 \pm 26,848	75.1 \pm 20.0
Uninoculated SHa	7	D-N	207 \pm 1,709	593 \pm 115	ND ^b
SHa inoculated with Sc237 prions	7	D-N	156,781 \pm 22,899	118,525 \pm 20,999	75.6 \pm 13.4

^aCDI values were obtained from denatured samples of Syrian hamster (SHa) brain, as described.²¹⁰ The values are the mean \pm SD calculated from seven independent experiments. PTA precipitation was performed without PK digestion, and the pellet was resuspended to the original volume and assayed in the direct CDI for PrP using Eu-labeled recHuM-P Fab.

^bThis percentage was not calculated due to frequent negative value of either the numerator or the denominator.

FIGURE 76.13. Correlation between the conformation-dependent immunoassay (CDI) and bioassay in Tg mice. Sandwich CDI protocol for the detection of the disease-causing prion protein isoform (PrP^{Sc}) was compared to titration bioassays in Tg(MHu2M)5378/*Pmp*^{0/0} mice for three spontaneous Creutzfeldt-Jakob disease (sCJD) brains (**A**) and one familial CJD (fCJD) brain (**B**). Samples were precipitated with phosphotungstic acid (PTA) and digested with 2.5 μ g per mL PK at 37°C for 1 hour. The MAR1 mAb²¹ was used for capture, and Eu-labeled 3F4 mAb was used for detection. The (D – N) values measured in counts per minute (cpm) are directly proportional to the concentration of PrP^{Sc}.^{333,337} Data points and bars represent the average \pm standard deviation (SD) obtained from three to four independent measurements. The cut-off (D – N) value of 1,789 cpm for this sandwich CDI protocol was calculated by [mean + 3(SD)] and determined from 100 brain samples obtained from patients who died from nonneurologic disease ($n = 6$), Alzheimer's disease ($n = 7$), and other neurologic diseases ($n = 5$). Diagnosis of human prion disease. *Proc Natl Acad Sci U S A* 2005;102:3501–3506, with permission; copyright © 2005 National Academy of Sciences, USA.)

The identification of BSE-positive cattle in Canada and the United States has prompted increased surveillance in these countries, but the number of cattle tested remains less than 2% of the annual slaughter.³⁰⁶ Despite the small number of cattle being tested, new cases of BSE are still being found. These new cases are often attributed to tainted feed by agriculture authorities, who continue to think of prion diseases as being similar to infectious illnesses caused by viruses or bacteria. Some officials want to believe that BSE will disappear once the use of ruminant-derived feed ceases. Most cases of prion disease are likely to be sporadic. In Japan, ~4 million cattle were tested over 4 years, and ~20 cases of BSE have been identified. Two Japanese cows with BSE, one age 21 months and the other age 23 months, have been identified.⁴⁴² It seems likely that most or all of these young animals developed sporadic BSE.

Determining how early in the incubation period prions can be detected by bioassay is possible due to the construction of Tg(BoPrP)*Prnp*^{0/0} mice.^{49,352} Prior to the production of Tg(BoPrP)*Prnp*^{0/0} mice, cattle were used for bioassays of bovine prions. In a limited study using cattle bioassays, bovine prions were undetectable in the obex of the brainstem until 26 months after oral inoculation.⁴²⁰ In these studies, prion infectivity was detected much earlier in the lymphoid tissue of the distal ileum.

MOLECULAR PATHOGENESIS OF PRION DISEASES

In the prion diseases, PrP^{Sc} accumulates in the CNS and triggers presynaptic bouton degeneration, dendritic atrophy, vacuolation of neurons, and hypertrophy of astrocytes.¹⁷⁸ Kinetic studies following the development of prion disease have identified a stereotypical progression of neurodegeneration.³³ Following initiation of prion replication in a group of neurons, PrP^{Sc} spreads to other neurons and to other brain regions by anterograde transport to axon terminals. This is followed by presynaptic bouton degeneration and dendritic atrophy, and later by nerve cell death. Interestingly, neurodegeneration caused by prions requires PrP^C expression. When *Prnp*^{0/0} mice were implanted with neuronal grafts from wt mice and inoculated with prions, only the grafts exhibited neuropathology despite the deposition of PrP^{Sc} throughout the CNS.³⁷

Apoptosis in Prion Diseases

In both scrapie and CJD, cell death has been attributed to apoptosis. In one study, purified PrP^{Sc} was reported to cause the death of cultured cells.³⁰¹ In another study, PrP^{Sc} was shown to induce the release of Ca²⁺ from the endoplasmic reticulum (ER) and activate caspase-12.¹⁵⁷

Dendritic Atrophy and Notch-1

To investigate the molecular events that underlie dendritic atrophy, the expression of β -catenin, which initiates dendritic growth and maturation,⁴⁴⁴ and Notch-1, which inhibits their growth and maturation during neuronal development and causes regression of mature dendrites,³¹⁹ were studied. In neurons of prion-infected mice, increased levels of the Notch-1 intracellular domain (NICD) accompanied dendritic atrophy.¹⁷² Elevated levels of NICD were also found in ScN2a cells compared to uninfected (N2a) control cells. To determine if Notch-1 activation has a role in the shortening of neuronal

processes, ScN2a cells were transfected with a Notch-1 small interfering (si) RNA. The siRNA rescued the normal, long-neurite phenotype, suggesting that Notch-1 activation mediates dendritic atrophy in prion disease.

Neurotoxic PrP Molecules

It is important to distinguish between neurodegeneration caused by PrP^{Sc} and that produced by a toxic, mutant PrP molecule. For example, some PrP molecules with internal deletions²⁶⁷ and others with N-terminal truncations have been shown to be neurotoxic.³⁵⁹ In general, these PrP molecules are unable to support prion propagation. The smallest toxic PrP molecule synthesized to date is a 21-mer consisting of residues 106 to 126.¹¹² Recently, a 61-mer produced after deletion of residues 23 to 88 and 141 to 221 was found to be neurotoxic. Studies in Tg mice showed that expression of this 61-mer peptide caused ataxia. Neuropathologic examination found PrP accumulation in the CNS and neuronal apoptosis,³⁸⁵ but the disease could not be transmitted to wt rodents or Tg mice. To date, the smallest PrP molecule capable of supporting prion replication remains an N-terminally truncated PrP with an internal deletion, designated PrP106.³⁸⁴

The PrP paralog Dpl causes a toxic form of neurodegeneration and is unable to support prion replication. Both Dpl-induced neurodegeneration and that mediated by PrP carrying an N-terminal deletion from residues 32 to 134 were prevented by coexpression of wt PrP.^{262,359}

Transmembrane PrP Molecules

Based on cell-free translation studies, PrP^C seems able to be folded into three different forms: ^{Ntm}PrP, ^{Ctm}PrP, and ^{Sec}PrP.¹⁵⁴ ^{Ntm}PrP and ^{Ctm}PrP span the lipid bilayer once via a highly conserved hydrophobic region at the center of the molecule (residues 111–134) with either the N-terminus or C-terminus, respectively, on the extracytoplasmic side of the membrane. These two conformers are generated in small amounts (<10% of total PrP) as part of the normal biosynthesis of wt PrP in the ER. Mutations within or near the transmembrane domain increase the relative proportion of ^{Ctm}PrP to as much as 30% of total PrP.³⁷⁸ The ^{Ntm}PrP conformer spans the membrane with N-terminus in the ER lumen.

^{Ctm}PrP is hypothesized to be a key pathogenic intermediate in both familial and infectious prion diseases. Tg mice expressing PrP(A117V) or another ^{Ctm}PrP-favoring mutation, such as AV3 (with three alanine-to-valine substitutions at residues 113, 115, and 117), synthesize ^{Ctm}PrP in their brains and spontaneously develop neurologic dysfunction without detectable PrP^{Sc} or prion infectivity. The brain from a GSS patient with the PrP(A117V) mutation contained high levels of ^{Ctm}PrP.¹⁵⁴ In addition, a proteolytic fragment of ^{Ctm}PrP was found to be increased on the surface of cells expressing the P101L mutation.²⁵⁸ Taken together, these observations suggest that ^{Ctm}PrP may represent an alternative pathogenic form of PrP in some inherited prion diseases.

Subsequent studies showed that ^{Ctm}PrP has an uncleaved, N-terminal signal peptide.³⁷⁸ Substitution of a charged residue for a hydrophobic residue within the signal sequence (L9R) increased the proportion of ^{Ctm}PrP to ~50% during cell-free translation. Combining the L9R mutation with the AV3 mutation in the transmembrane domain resulted in a protein that was synthesized exclusively as ^{Ctm}PrP, in both cell-free translation reactions and transfected cells.³⁷⁸

SPORADIC HUMAN PRION DISEASES

In most patients with CJD, there is neither an infectious nor a heritable etiology. How prions arise in patients with sCJD is unknown. Various hypotheses include (a) horizontal transmission from humans or animals,¹²⁰ (b) somatic mutation of the *PRNP* ORF, (c) spontaneous conversion of PrP^C into PrP^{Sc}, and (d) the accumulation of PrP^{Sc}, which is normally present at undetectable levels. Numerous attempts to establish an infectious link between sCJD and a preexisting prion disease in animals or humans have been unrewarding.⁸⁶ Only in the case of vCJD has a link between prion-infected cattle and human prion disease been established.⁴²⁹

Studies demonstrating the formation of prions from the synthetic peptide PrP(89–143,P101L) and from recombinant PrP(89–230) in cell-free systems argue for the spontaneous generation of prions in mammals.⁷⁸ These findings provide an explanation for the sporadic forms of prion disease, for which extensive epidemiologic studies failed to identify an exogenous source of prions.⁸⁶ The spontaneous generation of prions from within a host is in stark contrast to viral infections, which can generally be traced to an exogenous source. Therefore, the cell-free generation of prions forces us to conclude that spontaneous conversion of PrP^C to PrP^{Sc} is a plausible explanation for sporadic prion disease in any mammal expressing PrP^C.

HERITABLE HUMAN PRION DISEASES

The recognition that 10% to 15% of CJD cases are familial (f) led to the suspicion that genetics plays a role in this disease. Subsequently, transmission of fCJD to apes and monkeys was reported.^{240,328} More than 40 different mutations of the PrP gene have been identified, of which 35 are point mutations and the remainder are octarepeat expansions or deletions (Fig. 76.11); see reviews.^{249,410} Five mutations have been genetically linked to inherited human prion diseases (Table 76.3). Virtually all cases of GSS and fatal familial insomnia (FFI) appear to be caused by germline mutations in the PrP gene. The brains of patients with inherited prion disease contain infectious prions that have been transmitted to experimental animals.

Gerstmann-Sträussler-Scheinker and Genetic Linkage

The transmissibility of GSS, a familial disease, to apes and monkeys was demonstrated at a time when most investigators believed that scrapie, CJD, and related disorders were caused by viruses.²⁴⁰ With the discovery that the P102L mutation of the human PrP gene was genetically linked to GSS, prion diseases were proposed to be both genetic and infectious disorders.¹⁶⁴ The P102L mutation was linked to the development of GSS with a logarithm of the odds (LOD) score exceeding 3, demonstrating a tight association between the altered genotype and disease phenotype.

Familial Creutzfeldt-Jakob Disease Caused by Octarepeat Inserts

An insertion of 144 bp containing six octarepeats at codon 53, in addition to the five that are normally present, was described in patients with CJD from four families residing in southern England.³⁰² Genealogic investigations showed that all four

families are related, arguing for a single founder born more than two centuries ago. The LOD score for this extended pedigree exceeds 11. Studies from several laboratories have demonstrated that inserts of two, four, five, six, seven, eight, or nine octarepeats, in addition to the normal five, are found in individuals with inherited CJD (Fig. 76.11). Tg mice expressing an expanded number of octarepeats develop neurodegeneration, but brain extracts have failed to transmit disease to inoculated recipients.⁷¹

To study the mechanism by which octarepeat expansions cause inherited prion disease, PrP peptides composed of residues 23–27 coupled to amino acids 60–91 comprising the four octarepeats (PHGGGWHQ) were studied by electron paramagnetic resonance (EPR) after being titrated with Cu²⁺ ions.¹³ The “wild-type” synthetic peptide with four octarepeats showed high Cu²⁺ occupancy, favoring the binding of one Cu²⁺ per His residue within an octarepeat as measured by EPR. Expanding the PrP peptide by adding up to four additional octarepeats did not alter the Cu²⁺ occupancy, but five or more additional octarepeats (totaling 9 or more repeats) shifted the Cu²⁺ binding from a high to a low occupancy state. This shift in Cu²⁺ occupancy correlates well with the age of onset of fCJD: for large octarepeat expansions resulting in nine or more repeats, the onset of CNS dysfunction was between ages 20 and 55.³⁷⁷ Eight or fewer octarepeats caused fCJD with an onset after age 55.

Familial Creutzfeldt-Jakob Disease in Libyan Jews

The unusually high incidence of CJD among Israeli Jews of Libyan origin was believed to be due to the consumption of lightly cooked sheep brain or eyeballs.¹⁸² Molecular genetic investigations revealed that Libyan and Tunisian Jews with fCJD have a point mutation at codon 200, resulting in a Glu → Lys substitution (Fig. 76.11).^{140,166} The E200K mutation has been genetically linked to fCJD, with an LOD score exceeding 3¹¹⁹; the same mutation has also been found in patients from many other families.¹⁴⁰ Life table analyses of carriers harboring the E200K mutation exhibit complete penetrance. Therefore, if the carriers live long enough, they will all eventually develop prion disease.

Fatal Insomnia

The D178N mutation has been linked to the development of FFI, with an LOD score exceeding 5. More than 30 families worldwide with FFI have been recorded.²⁰³ With the D178N pathogenic mutation, the amino acid at polymorphic residue 129 alters the clinical and neuropathologic phenotype. The D178N mutation combined with M129 results in FFI. In this disease, adults generally older than 50 years present with a progressive sleep disorder and usually die within 1 year. In their brains, deposition of PrP^{Sc} is confined largely within the anteroventral and the dorsal medial nuclei of the thalamus. In contrast, the same D178N mutation with V129 produces fCJD, in which the patients present with dementia and widespread deposition of PrP^{Sc} is found postmortem. The first family to be recognized with CJD was found to carry the D178N mutation.²⁰⁹

Tg mice expressing mutant PrP(D178N) had a normal lifespan, but old Tg mice exhibited cerebellar vacuolation and increased glial fibrillary acidic protein (GFAP) deposition in both

the thalamus and cerebellum.¹⁷⁴ No increased PrP deposition, as judged by IHC, was reported and no protease-resistant PrP was seen on western blots except when a 40-fold increase in protein was digested before gel electrophoresis. CNS dysfunction could be transmitted to mice overexpressing wt PrP^C after intracerebral inoculation, with incubation periods ranging between 300 and 500 days.

Human PrP Gene Polymorphisms

The Met/Val polymorphism at codon 129 (Fig. 76.11) appears to influence expression of the inherited, as well as the iatrogenic and sporadic, forms of prion disease.²⁷⁹ Most Caucasian patients with sCJD are homozygous for Met or Val at codon 129; this contrasts with the general Caucasian population among which 51% are Met/Val heterozygotes. In the Japanese population where the frequency of the Val allele is low, heterozygosity in Japanese sCJD patients was almost as frequent as in the general Japanese population.³⁹⁷

A second polymorphism resulting in an amino acid substitution at codon 219 (Glu/Lys) has been reported to occur with a frequency of approximately 12% in the Japanese population but not in Caucasians.¹⁹⁷ Studies of cultured cells and Tg mice expressing PrP(K219) argue that the Lys substitution produces dominant-negative inhibition. Presumably, PrP^C(K219) binds to protein X, which prevents PrP^C(E219) from being converted into PrP^{Sc}.^{187,294}

Two other polymorphisms have been identified. The third polymorphism results in an amino acid substitution at codon 171 (Asn/Ser),¹⁰⁹ which lies adjacent to the putative protein X binding site. The deletion of a single octarepeat (24 bp), which has been found in 2.5% of Caucasians, represents another polymorphism in the human PrP gene.²¹³ In another study of more than 700 individuals, this single octarepeat deletion was found in 1.0% of the population.

INFECTIOUS HUMAN PRION DISEASES

Prions from different sources have infected humans. Human prions have been transmitted to others both by ritualistic cannibalism and iatrogenic means. Kuru in the highlands of New Guinea was transmitted by ritualistic cannibalism, as people in the region attempted to immortalize their dead relatives by eating their brains.⁵ Iatrogenic transmissions include prion-tainted human growth hormone (HGH) and gonadotropin, dura mater grafts, and corneal transplants from people who died of CJD. In addition, CJD cases have been recorded after neurosurgical procedures in which ineffectively sterilized depth electrodes or instruments were used. As described below, vCJD resulted from the transmission of BSE prions through the ingestion of tainted beef products.⁴²⁸

Human Growth Hormone

More than 165 young adults have been diagnosed with iatrogenic CJD (iCJD) between 4 and 30 years after receiving HGH or gonadotropin from cadaveric pituitaries.^{255,429} The longest incubation periods (20–30 years) are similar to those associated with more recent cases of kuru.^{4,198} Since 1985, recombinant HGH produced in *E. coli* has been used in place of cadaveric HGH. With recombinant HGH, no cases of iCJD have been identified.

Variant Creutzfeldt-Jakob Disease

The first cases of vCJD in teenagers and young adults were identified in Great Britain in 1994.^{429,430} More than 215 teenagers and young adults have died of vCJD. The majority of vCJD patients presented with psychiatric symptoms including dysphoria, withdrawal, anxiety, insomnia, and loss of interest.⁴²⁹ Generally, neurologic deficits did not appear until at least 4 months later; these neurologic changes consisted of memory loss, paresthesias, sensory deficits, gait disturbances, and dysarthria.

As of March 2011, vCJD cases have been reported from the following countries: 175 from the United Kingdom; 25 from France; 5 from Spain; 4 from Ireland; 3 each from the United States and The Netherlands; 2 each from Portugal, Canada, and Italy; and one each from Japan, Taiwan, and Saudi Arabia. Two of the three U.S. cases, two of the four cases from Ireland, and the single cases from Canada and Japan were likely exposed to the BSE agent while residing in the United Kingdom. One of the 25 French cases may also have been infected in the United Kingdom. Although the average age of vCJD patients is 26 years, the youngest patient was 12 years old and the oldest was 74 years of age. The median duration of illness was 13 months, with the range from 6 to 69 months.

In addition to the young age of these patients, vCJD is characterized by numerous PrP amyloid plaques surrounded by a halo of intense spongiform degeneration in the brain.¹⁷¹ These unusual neuropathologic changes have not been seen in CJD cases in the United States, Australia, or Japan.^{64,171} Both macaques and marmosets developed neurologic disease several years after inoculation with bovine prions,¹⁶ but only the macaques exhibited numerous PrP plaques similar to those found in vCJD.²¹⁴

From both epidemiologic and experimental studies, evidence is now compelling that vCJD is the result of prions being transmitted from cattle with BSE to humans through consumption of contaminated beef products.

Transmission of Variant Creutzfeldt-Jakob Disease Prions by Blood Transfusion

vCJD has been identified in three patients who received blood transfusions from donors who later died of vCJD. In one case, the recipient was a 69-year-old man who was transfused 6.5 years before the onset of neurologic dysfunction.²²⁴ His PrP gene encoded Met/Met at position 129. Many details of the second case are not published, but the patient is known to have died of a nonneurologic disease.²⁸⁸ Although vCJD prions were found in the spleen and cervical lymph nodes of this patient, none were found in the brain. The patient's PrP gene encoded Met/Val at position 129 and, as such, is the first heterozygous codon 129 human identified with vCJD prions.

A glimpse of future vCJD cases caused by prion-tainted transfused blood may come from a survey of tissues collected during appendectomies and tonsillectomies. This U.K. survey reports that of the 12,674 appendectomy specimens examined, 3 were positive for PrP^{Sc} by IHC.¹⁵⁹ This finding argues that as many as 3,800 people in the United Kingdom may be replicating vCJD prions in their lymphoid tissues. Because IHC is considerably less sensitive than some ELISA-based assays, the number of Britons harboring vCJD prions in their lymphoid tissues may prove to be numerous.³³⁵ As noted above, 15 of 21 people in the United Kingdom who died of vCJD were found to have detectable PrP^{Sc} in their blood using a capture ELISA format.¹⁰³

STRAINS OF PRIONS

That goats with scrapie can manifest two different syndromes, one in which the goats became hyperactive and the other in which they became drowsy, raised the possibility that strains of prions might exist.²⁸⁷ Subsequent studies with mice documented the existence of multiple strains through measurements of incubation times and the distribution of vacuoles in the CNS.^{98,115}

Many investigators argued prion strain-specific information must be encoded in a small nucleic acid,⁴¹ but none was ever found.³³⁶ Others argued that this information must be enciphered within the structure of PrP^{Sc}.³⁰⁷ The first evidence supporting the hypothesis that strain-specific information is enciphered in PrP^{Sc} came from studies on prions causing transmissible mink encephalopathy (TME), which were passaged into Syrian hamsters. On serial passaging, two strains emerged: One strain (HY) produced hyperactivity in Syrian hamsters and the other (DY) was manifest as a drowsy syndrome, as was seen with scrapie strains in goats.²⁶ The HY strain is similar to the Sc237 prion strain with respect to protease resistance and sedimentation properties, whereas the DY strain shows minimal protease resistance and is less readily sedimented.²⁵

In subsequent binding protection studies, PrP^{Sc} from HY- or DY-infected hamster brains was mixed with labeled PrP lacking a GPI anchor that was produced in mammalian cells.²³ The labeled PrP bound to PrP^{Sc}, and the relative resistance to proteolytic digestion of the labeled PrP reflected that of PrP^{Sc}. Whether the protease resistance of the labeled PrP is the result of binding to PrP^{Sc} or is due to a change in the conformation of the labeled PrP itself remains to be determined.

Because the HY and DY strains emerged after passaging TME prions in Syrian hamsters, concern over the origin of these strains made the conclusions somewhat questionable. Such concerns were mollified by studies on the transmission of FFI and fCJD to Tg mice. Prions were generated *de novo* in patients harboring PrP gene mutations and propagated in mice expressing chimeric mouse-human (MHu2M) PrP. Brain homogenates of FFI and fCJD(E200K) patients transmitted disease to Tg(MHu2M) mice approximately 200 days after inoculation. The FFI inoculum induced formation of a 19-kD PrP^{Sc} fragment, as measured by sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE) after limited proteolysis and deglycosylation; in contrast, fCJD(E200K) produced a 21-kD PrP^{Sc} fragment.⁴⁰¹ On second passage, Tg(MHu2M) mice inoculated with FFI prions showed an incubation time of approximately 130 days and a 19-kD PrP^{Sc}

fragment, whereas those inoculated with fCJD(E200K) prions exhibited an incubation time of approximately 170 days and a 21-kD PrP^{Sc} fragment.³⁰⁹ These findings demonstrated that MHu2M PrP^{Sc} can exist in two different conformations, based on the sizes of the protease-resistant fragments, and argue that PrP^{Sc} acts as a template for the conversion of PrP^C into nascent PrP^{Sc}.

Studies with Tg mice also demonstrated that the prions causing BSE and vCJD are similar, but distinct from those responsible for sCJD, iCJD, and fCJD(E200K). Both BSE and vCJD prions transmitted to Tg mice expressing BoPrP after ~250 days, whereas mice expressing either HuPrP or MHu2M PrP developed disease after more than 500 days.^{158,206,352} Moreover, sCJD, iCJD, and fCJD(E200K) prions failed to transmit disease to Tg(BoPrP) mice after more than 500 days (Table 76.8).³⁵⁰

Isolation of New Strains

Many examples of new strains of prions arising upon passage into a host expressing a foreign PrP gene have been documented. Initially, this was observed when prions propagated in one species were passaged into another species.¹⁹⁴ New strains pathogenic to Syrian hamsters were obtained from prion strains that had previously replicated in mice after limiting dilution.³⁴⁹

Tg mice expressing MH2M PrP were inoculated with the two Syrian hamster prion strains, Sc237 and DY.²⁹¹ On first passage in Tg(MHM2)Prnp^{0/0} mice, the SHa(Sc237) prions exhibited prolonged incubation times, typical of a species barrier. On subsequent passage in Tg(MHM2)Prnp^{0/0} mice, the MH2M(Sc237) strain showed shortening of the incubation time. Moreover, the PrP^{Sc} of the MH2M(Sc237) strain exhibited structural properties differing from those of the parental SHa(Sc237) strain. Conversely, transmission of SHa(DY) prions to Tg(MHM2)Prnp^{0/0} mice did not encounter a species barrier, and the MH2M(DY) strain retained the conformational and phenotypic properties of SHa(DY).

Although cell-free models for mammalian prion propagation are still poorly understood, they have recently been applied to the study of prion strains. The highest yields for *in vitro* propagation have been achieved by seeding normal brain homogenate with prions and applying repeated rounds of sonication, that is, PMCA.⁵⁶ Although sonication introduces a series of problems, such as heterogeneous protein denaturation and high well-to-well variability in the generation of PrP^{Sc}, PMCA is currently the only cell-free method that converts PrP^C into an infectious form in substantial yields.

TABLE 76.8 Transmission of CJD Prions to Transgenic Mice

Prion inocula	Incubation period (mean days ± SEM; n/n ₀)		
	Tg(MHu2M)	Tg(MHu2M,M165V,E167Q)	Tg(BoPrP)
sCJD	197 ± 4 (24/24)	110 ± 2 (42/42)	>500 (58/58)
vCJD	605 ± 118 (6/14)	358 ± 17 (13/13)	267 ± 4 (80/80)
fCJD	170 ± 2 (10/10)	109 ± 3 (8/8)	>500 (2/36)
BSE	>500 (16/16)		240 ± 5 (41/41)

n, number of mice developing prion disease; n₀, number of mice inoculated.

In studies of the polymerization of recPrP into amyloid fibrils, several new approaches to the investigation of prion strains have emerged. Tg9949 mice, which overexpress MoPrP(89–231) and are not genetically predisposed to develop prion disease, were infected with recPrP (wt PrP residues 89–230) refolded into an amyloid conformation.²²⁰ The prion strain recovered from the brains of these mice was denoted MoSP1 and was transmissible to wt mice by serial passage.²²⁰ MoSP1 was readily distinguished from naturally occurring prions due to its high conformational stability.²²¹ During two subsequent rounds of serial passage, the incubation period (measured from inoculation to onset of neurological dysfunction) of MoSP1 isolates decreased from more than 500 days to 177 days in Tg9949 mice.²²² Strikingly, each shortening of the incubation period was accompanied by a decrease in the conformational stability of PrP^{Sc}.²²² No evidence suggesting that Tg9949 mice spontaneously generate prions was found, despite extensive experimentation, including repeated serial passage of three aged Tg9949 mouse brains as well as the examination of more than 50 Tg9949 brains by biochemical analysis and more than 100 Tg9949 brains by neuropathologic analysis.⁷⁷

Biochemical analysis of prions obtained from infected animals has given some insight into the structural variations that make up different strains. These variations include differences in glycosylation patterns, extent of protease resistance, electrophoretic mobility of proteolytic fragments, and conformational stability.^{24,129,333} However, the ability to modulate prion strain phenotypes purposefully by altering the conformation of PrP has only recently been demonstrated: recPrP folded into distinct amyloid conformations gave rise to distinguishable prion strains, with incubation periods that were dependent on the conformational stability of the recPrP amyloid.⁷⁷ By altering the conditions used to refold recPrP, amyloids with different conformational stabilities emerged. These amyloids were then inoculated into mice that overexpressed full-length

PrP at four-fold compared to wt levels. This resulted in prion strains with incubation periods and conformational stabilities that were correlated to the stability of the amyloid fibrils used to inoculate the mice (Fig. 76.14). The inability to infect wt mice directly with these preparations may reflect the low infectivity titers of such preparations or indicate that unidentified properties, in addition to conformational stability, modulate incubation period. Conflicting results using hamster prion strains with conformational stabilities that cover a much narrower range, compared to the synthetic prions studies, also support this notion.¹⁵ Nonetheless, the direct demonstration of the conformational basis of prion strain diversity provides further evidence that synthetic prions originate from the recPrP amyloid preparations, and not from the host or from contamination. If prions were arising spontaneously in the host, one would expect the strain properties to be independent of the amyloid properties. Exhaustive negative controls, including inoculation of the host mice with control solutions, biochemical and neuropathologic analysis of age-matched controls, and serial passage of aged brains from the host mice, also excluded spontaneous prion generation and contamination.⁷⁷

Recombinant PrP amyloids inoculated into Tg mice that overexpressed an N-terminally truncated PrP resulted in novel protease-sensitive, synthetic prions.⁷⁹ In contrast, many naturally occurring prions contain some fraction of PrP^{Sc} in a conformation that resists protease digestion (protease-resistant PrP^{Sc}, or rPrP^{Sc}).²⁴⁶ This observation has led to the idea that protease resistance is equated with prion infectivity and pathogenesis. However, many naturally occurring prion strains also contain PrP^{Sc} in a conformation that is sensitive to protease digestion (sPrP^{Sc}).^{121,333} The protease-sensitive, synthetic prion strains that were generated demonstrate that sPrP^{Sc} is transmissible and pathogenic, and can occur as a distinct entity from rPrP^{Sc}. Furthermore, repeated serial passage of these strains never resulted in the formation of rPrP^{Sc}, arguing that sPrP^{Sc} neither gives rise to nor results from rPrP^{Sc}.

FIGURE 76.14. The properties of new synthetic prion strains are modulated by the conformational stability of amyloids used to generate them. GdnHCl_{1/2} values of synthetic prion strains directly correlated to the GdnHCl_{1/2} values of the respective amyloid preparations (**A**: $R = 0.94$, $n = 9$, $P = 0.0002$), as well as to incubation periods (**B**: dashed line from ref. 222) in Tg4053 mice (○; $R = 0.993$, $n = 6$, $P < 0.0001$) and FVB mice (□; $R = 0.994$, $n = 3$, $P = 0.07$). The synthetic prions strains inoculated were: MoSP5 (blue), MoSP6 (green), MoSP7 (orange), MoSP9 (yellow), MoSP12 (lime), MoSP13 (purple). (Reprinted from Colby DW, Giles K, Legname G, et al. Design and construction of diverse mammalian prion strains. *Proc Natl Acad Sci U S A* 2009;106:20417–20422, with permission; copyright © 2009 National Academy of Sciences, USA.)

Exposing amyloid fibers formed from recPrP of hamster sequence to heat in the presence of brain homogenate or albumin also led to the generation of a novel prion strain named SSLOW (for ‘Synthetic Strain Leading to OverWeight’).²³¹ Hamsters inoculated with amyloid fibers prepared in this way did not show symptoms of disease during 661 days of observation following inoculation, but were found to have low levels of PrP^{Sc} in their brains upon termination of the experiment. A serial transmission caused disease in more than 480 days. Biochemically, SSLOW had a conformational stability comparable to naturally occurring prion strains. However, the disease phenotype reported was unusual, in that it included weight gain and an unusually slow disease progression. Given the biochemical similarities between SSLOW and naturally occurring prions, the conformational basis of this unusual strain phenotype remains to be determined.

A central issue in the generation of prions from recombinant protein has been the presumed low titers of infectivity in the amyloid fibers formed,²⁴⁴ which results in long incubation times and often the inability to infect wt rodents directly. If long incubation times do in fact result from low titers, then this implies that synthetic prion preparations are heterogeneous mixtures containing many different conformations, and thus, limits their usefulness for determining the structure of PrP^{Sc}. Alternatively, long incubation times may indicate that amyloid fibers require maturation or further adaptation of their conformation in order to become fully infectious.

Several laboratories have succeeded in creating prion infectivity under conditions developed for PMCA.^{18,93,413} The initial report for the spontaneous generation of infectivity came in the form of unexpected amplification of prions in negative controls during studies that aimed to identify minimal components necessary for prion amplification *in vitro*.⁹³ The components required for amplification included polyanions in addition to PrP^C, which was accompanied by co-purified lipids. These results were verified by repeating the experiment in a laboratory that had never been used for prion research, reducing the potential for contamination. It was later shown that prions can be generated in a similar fashion using brain homogenate as the substrate, rather than minimal components, and that the newly created prion strain was distinct from a commonly used lab strain.¹⁸ Prions created in these studies using either PrP^C or normal brain homogenate had titers that were sufficient to infect hamsters with incubation periods of 113 to 168 days, whereas naturally occurring hamster prion strains can have incubation periods of 60–300 days.^{192,333}

Synthesis of highly infectious prions from recPrP has recently been reported using PMCA in the presence of lipids and RNA.⁴¹³ The infectivity of these preparations was said to be similar to that of naturally occurring strains, but these results remain unconfirmed despite the initial excitement surrounding this report.

Interplay Between the Species and Strains of Prions

The prion derives its PrP^{Sc} sequence, which encodes the species of the prion (Table 76.1), from the last mammal in which it was passed. Although the primary structure of PrP is likely to be the most important or even sole determinant of the tertiary structure of PrP^C, factors determining the conformation of nascent PrP^{Sc} are less well defined. Certainly, the PrP^{Sc} in

an inoculum functions as a template and, as such, it is important in determining the tertiary structure of nascent PrP^{Sc} molecules. One of the most instructive examples of the interplay between PrP^{Sc} sequence and conformation comes from transmission studies of BSE and vCJD prions to Tg mice (Table 76.8),³⁵⁰ some of which was reviewed previously. vCJD prions are composed of wt HuPrP^{Sc} that is folded into a conformation that favors binding to BoPrP^C over interactions with a variety of humanized transgene products, including HuPrP^C, MHu2M, and MHu2M(M165V,E167Q).^{14,204,350,352} Similarly, BSE prions display a greater affinity for BoPrP^C than for the humanized transgene products.^{14,350}

The foregoing studies demonstrate that the conformation of PrP^{Sc} can override differences in the PrP sequence between the infecting prion and host PrP^C. Such findings complicate the initially monastic view positing that the “species barrier” is the only determinant governing the transmission of prions from one species to another.²⁸⁵ It seems likely that defining the molecular language by which biological information is enciphered in the conformation of PrP^{Sc} will require determining the tertiary structures of PrP^{Sc} molecules isolated from many different strains.

PRION DISEASES OF ANIMALS

The prion diseases of animals include scrapie of sheep and goats, BSE, TME, chronic wasting disease (CWD) of mule deer and elk, feline spongiform encephalopathy, and exotic ungulate encephalopathy (Table 76.1).

PrP Polymorphisms in Sheep, Cattle, and Elk

In 1962, Parry argued that host genes were responsible for the development of scrapie in sheep. He was convinced that natural scrapie is a genetic disease that could be eradicated by proper breeding protocols.^{283,284} He considered its transmission by inoculation of importance primarily for laboratory studies and communicable infection of little consequence in nature. Other investigators viewed natural scrapie as an infectious disease and argued that host genetics only modulates susceptibility to an endemic infectious agent.⁹⁹

In sheep, PrP gene polymorphisms encoding amino acid substitutions at positions 136, 154, and 171 have been studied with respect to the incidence of scrapie (Fig. 76.11).^{76,141,212} Investigations of natural scrapie in the United States have shown that 85% of afflicted sheep are of the Suffolk breed. Only those Suffolk sheep homozygous for Gln at codon 171 developed scrapie, although healthy controls with Gln/Gln, Gln/Arg, and Arg/Arg genotypes were also found.^{76,143,273,423} These results argue that susceptibility to scrapie in Suffolk sheep is governed by the PrP codon 171 polymorphism; similarly, codon 171 as well as residue 136 in Cheviot sheep profoundly influences susceptibility to scrapie.¹⁶⁷

In contrast to sheep, different breeds of cattle have no specific PrP polymorphisms. The only polymorphism recorded in cattle is a variation in the number of octarepeats: most cattle, like humans, have five octarepeats but some have six. However, the presence of six octarepeats does not seem to be overrepresented in BSE.¹⁶⁸

In studies of CWD, the susceptibility of elk, but not deer, seems to be modulated by codon 132, which corresponds to

codon 129 in humans (Fig. 76.11). Elk with CWD consistently express Met/Met at position 132; no elk with CWD expressing leucine at this residue have been found.²⁷³

Bovine Spongiform Encephalopathy

Prion strains and the species barrier are of paramount importance in understanding the BSE epidemic in Britain, where it is estimated that between 1 and 2 million cattle were infected with prions.⁷ The mean incubation time for BSE is approximately 5 years. Therefore, most cattle did not manifest disease because they were slaughtered between 2 and 3 years of age. Nevertheless, more than 180,000 cattle, primarily dairy cows, died of BSE between 1986 and 2000.^{7,297} BSE is a massive common-source epidemic caused by meat and bone meal (MBM) fed primarily to dairy cows. MBM was prepared from the offal of sheep, cattle, pigs, and chickens as a high-protein nutritional supplement. In the late 1970s, the hydrocarbon-solvent extraction method used in the rendering of offal began to be abandoned, resulting in MBM with a much higher fat content.⁴²⁸ It is widely accepted that this change allowed scrapie prions from sheep to survive the rendering process and to be passed into cattle. Alternatively, bovine prions may have been present at low levels prior to modification of the rendering process and, with the processing change, survived in sufficient numbers to initiate the BSE epidemic when reintroduced into cattle through ingestion of MBM.²⁹⁷ Perhaps a particular conformation of BoPrP^{Sc} was selected for heat resistance during the rendering process and then reselected multiple times as cattle infected by ingesting prion-contaminated MBM were slaughtered and their offal rendered into more MBM. Against the latter hypothesis is the widespread geographic distribution of the initial 17 cases of BSE throughout England, which occurred almost simultaneously.⁴²⁸ It is noteworthy that brain extracts from cattle with BSE cause disease in cattle, sheep, mice, pigs, and mink after intracerebral inoculation.⁴¹⁹

In July 1988, the practice of feeding MBM to sheep and cattle was banned. Although statistical analyses demonstrate that the epidemic has disappeared as a result of this ruminant feed ban, reminiscent of the disappearance of kuru in the Fore people of New Guinea, it is unclear how many cases of BSE were due to infection and how many arose spontaneously.³⁰⁶ In 2003, there were 1,390 cases of BSE; how many were due to tainted feed is unknown. Although evidence of a preexisting prion disease of cattle, either in Great Britain or elsewhere, is scant, an outbreak of TME in Wisconsin has been cited as evidence for sporadic BSE.²³⁹ Moreover, the formation of synthetic prions from wt recPrP argues that any mammal expressing PrP^C can produce prions spontaneously.^{77,221}

Compelling Evidence for Transmission of Bovine Prions to Humans

The restricted geographic occurrence and chronology of vCJD raised the possibility that BSE prions were transmitted to humans. However, no set of dietary habits clearly distinguished vCJD patients from apparently healthy people, and there was no explanation for the predilection of vCJD for teenagers and young adults. It is noteworthy that epidemiologic studies since the mid-1970s failed to find evidence of transmission of sheep prions to humans.⁸⁶ Attempts to predict the future number of cases of vCJD, assuming exposure to bovine prions prior to

the offal ban, have been uninformative because so few cases of vCJD have occurred.¹³⁰

Studies of PrP^{Sc} from brains of patients who died of vCJD showed a PrP glycoform pattern different from those found for sCJD and iCJD,⁸¹ but the utility of measuring PrP glycoforms in trying to establish a relationship of BSE to vCJD has been questioned^{128,369} because PrP^{Sc} is formed after the protein is glycosylated and enzymatic deglycosylation of PrP^{Sc} requires denaturation.¹⁰⁶ Moreover, synthetic prions have been formed from unglycosylated recMoPrP(89–230), demonstrating that glycosylation is unnecessary for prion formation.^{77,220}

When non-Tg RIII mice were inoculated with human vCJD or bovine BSE prions, similar incubation times of approximately 310 days were observed.⁴³ This finding was used to argue for a relationship between vCJD and BSE. But such studies suffer from transmission of both BSE and vCJD prions to a heterologous host (i.e., non-Tg mice expressing MoPrP^C). Using Tg mice, it became possible to accumulate compelling evidence for the transmission of bovine prions to humans. BSE prions transmitted to Tg(BoPrP) mice after approximately 240 days but not to Tg mice expressing either HuPrP or MHu2M PrP (Table 76.8).³⁵² On second passage to Tg(BoPrP)Prnp^{0/0} mice, the incubation time was unaltered, demonstrating the complete absence of a species barrier. Similar to BSE prions, vCJD prions transmitted readily to Tg(BoPrP)Prnp^{0/0} mice, with a slightly longer incubation time of approximately 270 days (Table 76.8),³⁵² but poorly to Tg(HuPrP)¹⁵⁸ and Tg(MHu2M) mice.^{204,350} On second passage of vCJD prions to Tg(BoPrP)Prnp^{0/0} mice, the incubation time was reduced to approximately 225 days, demonstrating a small but expected species barrier. Moreover, sCJD, iCJD, and fCJD(E200K) prions failed to transmit disease to Tg(BoPrP)Prnp^{0/0} mice after more than 500 days.³⁵⁰ These findings argue that the strain-specific PrP^{Sc} conformations of BSE and vCJD prions are similar, despite substantial differences in the amino acid sequences of BoPrP and HuPrP. Clearly, the conformation of HuPrP^{Sc}(vCJD) makes these prions more readily transmissible to Tg(BoPrP)Prnp^{0/0} mice than to either Tg(HuPrP)Prnp^{0/0} or Tg(MHu2M)Prnp^{0/0} mice.³⁵⁰

Chronic Wasting Disease

Mule deer, white-tailed deer, and elk have been reported to develop CWD, which is the only prion disease known in free-ranging animals. CWD was first described in 1967 and reported to be a spongiform encephalopathy in 1978, based on histopathology in the brain. CWD has been found in the United States, Canada, and South Korea.

In the United States, CWD has been reported in Colorado, Wyoming, South Dakota, Nebraska, Oklahoma, Montana, New Mexico, Minnesota, Wisconsin, and New York. In captive cervid herds, up to 90% of mule deer have been reported to be positive for prions,⁴³⁶ and up to 60% of elk in Colorado and Wyoming develop CWD.⁴³⁵ Moreover, the incidence of CWD in cervids living in the wild has been estimated to be as high as 15%.²⁵⁴ The mode of transmission of CWD prions among mule deer, white-tailed deer, and elk is unresolved, but contamination of grass with prions in saliva or feces was hypothesized to be a likely source based on the high content of PrP^{Sc} in the intestinal lymphoid tissue of cervids with CWD.⁴³⁵ After feeding deer prions, we found that asymptomatic CWD-infected mule deer excrete CWD prions in their feces long before they develop clinical signs of prion

disease. Intracerebral inoculation of irradiated deer feces into Tg mice overexpressing cervid PrP revealed infectivity in 14 of 15 fecal samples collected from five deer at 7–11 months before the onset of neurological disease.³⁹² Although prion concentrations in deer feces were considerably lower than in brain tissue from the same deer collected at the end of the disease, the estimated total infectious dose excreted in feces by an infected deer over the entire incubation period may approximate the total contained in the brain.³⁹³ Prolonged fecal prion excretion by infected deer provides a plausible natural mechanism that explains the high incidence and efficient horizontal transmission of CWD within deer herds as well as prion transmission among other susceptible cervids. It is noteworthy that prions have also been detected in the saliva of cervids.^{152,242,270,394}

Brain homogenates from mule deer with CWD have transmitted disease to 4 of 13 cattle after intracerebral inoculation.¹⁵³ These findings are particularly important because there is great concern that CWD prions might be transmitted to cattle grazing in contaminated pastures. In addition, CWD has been transmitted to ferrets, mink, squirrel monkeys, goats, and mice after intracerebral inoculation⁴³⁵; however, only mule deer demonstrate efficient transmission of CWD prions by intracerebral inoculation. CWD has been transmitted from mule deer and elk to Tg mice expressing a cervid PrP gene.^{40,202,391} Such studies promise to increase substantially the understanding of prion disease in free-ranging animals. Whether CWD prions have been transmitted to deer hunters remains to be established.

FUNGAL PRIONS

Although prions were originally defined in the context of an infectious mammalian pathogen,³⁰⁸ the recognition that prions modify the metabolism of yeast has extended our understanding of these epigenetic elements. It is generally accepted that prions are elements that impart and propagate variability through multiple conformers of a normal, cellular protein. Nine prion determinants, [URE3], [PSI⁺], [PIN⁺]/[RNQ⁺], [MCA⁺], [SWI⁺], [OCT⁺], [MOT3⁺], [GAR⁺], and [ISP⁺] have been described in yeast^{70,425} and another prion determinant [HET-s] has been reported in the fungus *Podospora anserina*²³⁰ (see Chapter 22).

Some Differences Between Fungal and Mammalian Prions

A wealth of studies has now established the concept of prions in both mammals and fungi. Fungal prions do not form infectious particles and, as such, infection by exogenous prions does not generally occur. In contrast, prion infection in mammals can result from exposure to an exogenous inoculum and, like viruses, spread from one host cell to another. Fungal prions are produced in the cytoplasm, whereas mammalian PrP prions are produced within cholesterol-rich microdomains on the surface of cells, called rafts or CLDs.

In both fungi and mammals, synthetic prions have been formed from fragments of prion proteins that were forced to adopt β -sheet-rich conformations. These β -sheet-rich aggregates of prion protein fragments initiated prion replication when introduced into the appropriate fungal or mammalian host. Notably, different strains of both fungal and mammalian prions are distinct conformations of the particular prion pro-

tein. This finding necessitates a mechanism by which a distinct conformation can be templated and reproduced with a high degree of fidelity.

In the filamentous fungus *Podospora anserina*, the prion state of the HET-s protein initiates cell death through a process called heterokaryon incompatibility.¹⁴⁷ Filamentous fungi have several incompatibility loci that regulate the fusion of mycelium between genetically distinct individuals, one of these is the prion protein HET-s that has two-domains. The C-terminus is the prion domain (residues 218–289) that is required and sufficient for prion propagation; the N-terminus is the globular domain (residues 1–227) that specifies the incompatibility type. Solid-state NMR studies showed that the prion domain of HET-s in its fibrillar state forms a left-handed β -solenoid. Extended structural studies confirm six β -arcs, two salt bridges, and three asparagine ladders in the β -solenoid core.⁴¹¹ The β -solenoid is similar to the β -helix proposed for PrP^{Sc} based on EM crystallography studies and consistent with recent x-ray diffraction studies described above (see Fig. 76.10).

In yeast, the prion state is proposed to be functionally inert in the case of both [PSI⁺] and [URE3], and produces the same phenotype as inactivation of the maintenance gene. In contrast, prion diseases in mammals cannot be explained simply by the loss of function of PrP because ablation of the PrP gene does not produce neurodegeneration.^{46,87,234,334}

In studies of the rat hippocampus, a neuronal transcription factor called cytoplasmic polyadenylation element binding (CPEB) protein was found, which has an N-terminal region rich in Gln and Asn similar to the fungal prion domains. In *Aplysia*, the CPEB protein has been suggested to function as a prion in regulating protein synthesis in dendrites during long-term facilitation.³⁶² Interestingly, aggregated CPEB in the prion state appears to stimulate polyadenylation, whereas the monomer is much less active.³⁶¹ Undoubtedly, many more prions will be found throughout nature, some of which cause disease, whereas others function in the regulation of metabolism.

Similar to CPEB in that multimers are the biologically active form, the mitochondrial antiviral-signaling (MAVS) protein, which is required for innate immune defense against viruses, appears to be a prion.¹⁶² MAVS proteins form large aggregates after viral infection and these aggregates are potent activators of the IRF3 protein in the cytoplasm. MAVSs assemble into fibrous structures that convert endogenous MAVS proteins into more functional aggregates. This self-propagating process leads to the formation of nascent, biologically active MAVS aggregates and as such, MAVS is a prion. The MAVS aggregates produce a gain of function through a conformational switch that is highly efficient and tightly regulated by viral infection. Remarkably, *in vitro* incubation of retinoic acid-inducible gene I and mitochondria in the presence of K63 polyubiquitin chains efficiently converts endogenous MAVSs into functional MAVS prions.

PREVENTION AND THERAPEUTICS FOR PRION DISEASES

No therapeutics exist that halt or even slow neurodegeneration. The most effective drug that ameliorates the symptoms of a neurodegenerative disease is L-dopa, which was introduced in the mid-1960s.⁸⁵ Molecular genetics allows us to identify people at

risk for inherited neurodegenerative diseases decades before neurologic dysfunction is manifest, but no preventative therapeutics exist. Like the other inherited neurodegenerative diseases, the familial prion diseases are fully penetrant (see Fig. 76.11).^{65,372}

Prion Therapeutics

Various compounds have been proposed as potential therapeutics for treatment of prion diseases; these include polysulfated anions, dextrans, Congo red dye, oligonucleotides, and cyclic tetrapyrroles, all of which have been shown to increase survival time when given prior to prion infection in rodents, but not when administered a month or more after infection has been established.^{193,304,355}

In addition to studies in rodents, ScN2a cells chronically infected with scrapie prions have been used to identify a variety of compounds with antiprion activity,^{59,74,126,127,144,200,205,295,305,387,396} but none have been shown to be effective in halting prion diseases in either animals or humans except for N-(4-oxazol-5-yl-phenyl)-N'-pyridin-4-ylmethylene-hydrazine, referred to as Compound B.¹⁸⁹ Prolongation of the incubation time depended on the strain of prions as well as the time at which administration of Compound B was initiated. Moreover, the highly reactive phenylhydrazone structure of Compound B prevents it from becoming a drug.

Another approach has involved the search for small molecules that bind to PrP^C, the structure of which is known. *In silico* studies failed to identify any putative compounds likely to bind to PrP^C due to an absence of any exposed potential binding pockets. Despite these results, we developed several approaches to measure the binding of small compounds to purified recPrP.³⁰⁰ Isothermal titration calorimetry (ITC) was used to measure direct binding between the compounds and recPrP. We performed ITC with 16 confirmed antiprion compounds, but no substantial release of energy was detected for any of the compounds, suggesting that none interacted with recMoPrP(89–230). We next sought to measure the binding of compounds to recPrP by a thermal-denaturation upshift assay. The melting point of PrP was measured by circular dichroism (CD) in the presence of stabilizing and destabilizing agents. In accordance with the ITC results, none of the 16 compounds significantly increased the T_m of recMoPrP(89–230), suggesting that none of the compounds either stabilized or interacted with the folded domain of the protein.

Structure-based drug design based on dominant-negative inhibition of prion formation produced several lead compounds.²⁹⁵ Prion replication depends on protein–protein interactions, and a subset of these interactions gives rise to dominant-negative phenotypes produced by single residue substitutions.¹⁸⁷

A particularly interesting set of potential drugs is the branched polyamines, or dendrimers, which enhance the clearance of PrP^{Sc} from cells.^{128,387} Although these compounds cure cultured cells of prion infection, they have not been successfully deployed in mice because of difficulties in delivering such highly charged compounds into the CNS.

Inducible Transgenes as a Model for Therapeutics

Studies with inducible transgenes provide a model for prion therapeutics. Bigenic mice were constructed using a tetracycline-inducible PrP transgene system, in which doxycycline is capable

FIGURE 76.15. Both doxycycline dosage and levels of tetracycline-controlled transactivator (tTA) expression control the incubation time of RML prions in Tg(tTA:PrP)^{0/3} mice. Following the intracerebral inoculation of RML prions, Tg(tTA:PrP)^{0/3} mice (open circles), which express prion protein (PrP) at high levels in the brain, developed disease with an incubation period of approximately 149 days. Doubling the levels of PrP expression in Tg(tTA:PrP)^{0/3} mice (open diamonds) resulted in a shortening of the incubation period to 81 days, demonstrating that tTA controls PrP expression. Mice harboring only the target PrP transgene, designated Tg(tetO:PrP^{0/0}) mice (filled diamonds), became ill at ~433 days. The levels of PrP expression could be regulated in a dose-dependent manner by administration of doxycycline. Tg(tTA:PrP)^{0/3} mice treated with higher doses of doxycycline displayed longer incubation periods. To suppress cellular PrP (PrP^C) expression, animals received various concentrations of doxycycline in the drinking water beginning 7 days before intracerebral inoculation with RML prions. Bigenic Tg(tTA:PrP)^{0/3} mice were given doxycycline at concentrations of 0 (open circles), 0.002 (open squares), 0.02 (filled triangles), 0.2 (filled circles), and 2 (filled squares) mg ml⁻¹. (Reprinted, with permission, from Safar JG, DeArmond SJ, Kociba K, et al. Prion clearance in bigenic mice. *J Gen Virol* 2005;86:2913–2923, copyright © 2005 Society for General Microbiology.)

of suppressing approximately 95% of PrP expression. Bigenic mice inoculated with RML prions developed signs of disease approximately 80 days after inoculation, whereas bigenic mice maintained on oral doxycycline did not develop disease until approximately 450 days (Fig. 76.15).³³⁴ A dose-dependent relationship was found between the concentration of doxycycline in the drinking water and the prolongation of the incubation period: Higher doses of doxycycline produced longer incubation times. In earlier studies, the incubation times in prion-inoculated mice were prolonged by knockout of the PrP gene.^{233,312}

Studies with doxycycline argue that drugs diminishing the steady-state level of PrP^C are likely to be effective in treating prion disease. Such drugs might decrease transcription of the PrP gene or increase the degradation of PrP mRNA. Alternatively, an effective drug might diminish the synthesis of PrP^C or increase the clearance of PrP^C.

Another approach to controlling the expression of the PrP gene used the Cre/lox system to excise PrP-coding sequences in adult mice. Bigenic NFH-Cre/MloxP mice express PrP in neurons and nonneuronal cells until approximately 9 weeks of age, when they undergo Cre-mediated depletion of neuronal PrP^C.²³⁵ The NFH-Cre/MloxP mice were inoculated with RML scrapie prions at 3 to 4 weeks of age, and prion replication proceeded until Cre-mediated neuronal PrP^C depletion

occurred. At that time, early pathologic changes including spongiosis, gliosis, and PrP^{Sc} deposition were found. Over the next 4 weeks, these neuropathologic alterations resolved and the mice survived for more than 1 year despite the continued deposition of PrP^{Sc} in and adjacent to nonneuronal cells.

With *Prnp*^{+/-} mice that are heterozygous for ablation of the PrP gene, we and others found a marked prolongation of the incubation period after inoculation with RML prions.^{47,312} Although prion replication was somewhat slowed by a 50% reduction in PrP^C levels, the incubation time greatly lengthened. The cause of these longer incubation periods is unknown, but they may be due to changes in the location of the initial PrP^{Sc} deposition that occurs in *Prnp*^{+/-} mice.³¹² An alternative hypothesis suggests that the formation of some other form of PrP^{Sc} is uniquely delayed in *Prnp*^{+/-} mice, but no mechanism has been offered.³⁴⁰

Knockdown of PrP^C by RNAi⁴⁰³ resulted in a reduction of PrP^{Sc} in prion-infected cultured cells.⁸⁹ Lentivectors expressing PrP^C-specific short hairpin RNAs (shRNAs) that silence expression of *Prnp* were introduced into embryonic stem (ES) cells.²⁹⁶ Chimeric mice derived from lentivector-transduced ES cells expressed reduced levels of brain PrP^C by 15% to 70% depending on the degree of chimerism that ranged from 10% to 90%. The mean incubation period of the control mice was approximately 165 days, whereas those with less than 35% chimerism lived approximately 179 days and those with greater than 65% chimerism lived approximately 214 days. Extension of the incubation time by reducing PrP expression is consistent with studies using an inducible transgene controlled by doxycycline: the level of PrP expression was inversely proportional to the length of the incubation time.³³⁴

To explore the therapeutic potential of shRNAs, Tg mice at approximately 7 days of age were inoculated intracerebrally with RML prions and injected approximately 56 days later with lentivirus expressing an shRNA targeting PrP into the hippocampus bilaterally.⁴²⁶ In control mice not inoculated with prions, the PrP mRNA was reduced by approximately 75%. The prion-inoculated Tg mice that also received the lentivirus injections showed a modest, approximately 17-day prolongation of the incubation time, from 88 days to 105 days.

Quinacrine and Other Acridine Derivatives

Tricyclic derivatives of acridine exhibit half-maximal inhibition of PrP^{Sc} formation at effective concentrations (EC₅₀) between 0.3 and 3 μ M in cultured ScN2a cells.^{101,205} The EC₅₀ for chlorpromazine was 3 μ M, whereas quinacrine was 10 times more potent. Various 9-substituted, acridine-based analogs of quinacrine were synthesized, which demonstrated variable potencies similar to chlorpromazine and emphasized the importance of the side chain in mediating the inhibition of PrP^{Sc} formation.²⁰⁵ These studies showed that tricyclic compounds with an aliphatic side chain at the middle ring moiety constitute a new class of antiprion agents. Several bis-acridines proved to be 10 times more potent than quinacrine.²⁴³ However, the bis-acridines penetrated the blood–brain barrier (BBB) poorly and failed to extend the prion incubation time in mice.

Because quinacrine and chlorpromazine have been used for many years in humans as antimalarial and antipsychotic drugs, respectively, and are known to penetrate the BBB, such compounds became immediate candidates for the treatment of CJD and other human prion diseases.

Enthusiasm for quinacrine as an antiprion compound was considerable, since it was an U.S. Food and Drug Administration (FDA)–approved drug with a long history of administration to humans. Clinical trials of quinacrine in patients with CJD were initiated, since there were no effective drugs for the treatment of this uniformly fatal illness. Unfortunately, quinacrine was ineffective in treating humans dying of CJD⁸⁰ (M.G. Geschwind et al., unpublished data). Earlier studies demonstrated that quinacrine inefficiently penetrates the BBB, which could contribute to its lack of efficacy in mouse models of prion disease.^{17,82,124,445} Because quinacrine was found to be a substrate for P-glycoprotein (P-gp) multidrug resistance (Mdr1) transporters, we circumvented its poor BBB permeability by using Mdr1^{0/0} mice that are deficient in Mdr1a and Mdr1b genes encoding P-gps. Mdr1^{0/0} mice given oral quinacrine accumulated the drug in their brains up to 100 μ M without evidence of toxicity, a level approximately 100 times higher than that found in the brains of wt mice (Fig. 76.16¹²⁶). Moreover, brain levels of 100 μ M exceeded the EC₅₀ for quinacrine in ScN2a cells by more than 100-fold. Notably, an asymmetric carbon in the side chain of quinacrine creates two stereoisomers. (*S*)-quinacrine is two to three times more potent than the (*R*)-quinacrine enantiomer in cultured cells.³³⁰

Although PrP^{Sc} levels in the brains of prion-inoculated Mdr1^{0/0} mice decreased transiently upon the initiation of quinacrine treatment, the PrP^{Sc} levels rose after a couple of weeks despite the continued administration of quinacrine (Fig. 76.17¹²⁶). The transient depression of PrP^{Sc} levels in the Mdr1^{0/0} mice after initiating treatment with quinacrine did not result in a prolongation of the incubation time compared to untreated, control mice. A similar phenomenon was observed in cultured, prion-infected neuroblastoma cells: PrP^{Sc} levels initially decreased after quinacrine treatment and then rapidly recovered after 3 days of continuous treatment. The PrP^{Sc} that persisted in the brains of quinacrine-treated Mdr1^{0/0} mice showed a lower conformational stability and different immunofluorinities compared to that found in the brains of untreated controls. Because these altered physical properties were not maintained upon serial passage in Mdr1^{0/0} mice, we argued that quinacrine eliminates a specific subset of PrP^{Sc} conformers, resulting in the survival of drug-resistant prion conformations. The transient accumulation of this drug-resistant prion population provides a possible explanation for the lack of *in vivo* efficacy of quinacrine and other antiprion drugs.

Anti-PrP Antibodies

A panel of recombinant antibody fragments (recFabs), recognizing different epitopes on PrP, was studied with respect to inhibition of prion propagation in cultured ScN2a cells.²⁹⁰ Recombinant Fabs binding to PrP^C on the cell surface inhibited PrP^{Sc} formation in a dose-dependent manner. In ScN2a cells treated with the most potent recFab D18, prion replication was completely abolished and preexisting PrP^{Sc} rapidly cleared, suggesting that this antibody may cure established infection. The recFab D18 seem to recognize most of the PrP^C molecules on the cell surface, whereas other recFabs seem to bind fewer PrP^C molecules. In other studies, the monoclonal antibody, 6H4, which is believed to bind to the same region of PrP as recFab D18, was found to inhibit prion accumulation in ScN2a cells.¹⁰⁵

FIGURE 76.16. Accumulation of quinacrine in treated FVB and MDR^{0/0} mice. Quinacrine was given orally beginning 60 days postinoculation (dpi) for 30 d; the treated groups were designated FVB[60–90] and Mdr1^{0/0}[60–90]. The levels of quinacrine in the brains, kidneys, livers, and spleens of FVB[60–90] (white bars) and MDR^{0/0}[60–90] (black bars) were measured at 75 and 90 dpi by quantitative liquid chromatography tandem mass spectrometry and comparison to known standards. Error bars represent the standard error of the mean (n = 3). (Reprinted from Ghaemmaghami S, Ahn M, Lessard P, et al. Continuous quinacrine treatment results in the formation of drug-resistant prions. *PLoS Pathog* 2009;5:e1000673, with permission; copyright © 2009 Public Library of Science.)

Anti-PrP antibodies delivered systemically through transgenesis¹⁵⁶ or by injection^{364,425} were successful in blocking prion replication in mice inoculated intraperitoneally. The same anti-PrP antibodies were ineffective in treating prion infection initiated by intracerebral inoculation.

Whether antibodies or Fabs can be used for the prevention and treatment of prion diseases in humans or animals is unclear. Delivery of antibodies or Fabs to the CNS remains problematic due to the BBB. Notably, it seems unlikely that vaccination, which has been so effective in preventing many viral illnesses, will be a useful strategy for preventing or treating prion diseases.

Bioluminescence Imaging for Monitoring Drug Efficacy

Bioluminescence imaging (BLI) is based on the expression of a luciferase reporter gene driven by a promoter of interest. A sensitive CCD camera measures the luminescence signal following intraperitoneal (i.p.) injection of the substrate luciferin; light penetrates tissue and bone allowing *in vivo* monitoring. This technique allows mice to be repeatedly scanned throughout the disease process, enabling multiple data points to be collected on individual animals, each acting as its own control. Because

FIGURE 76.17. Levels of disease-causing prion protein isoform (PrP^{Sc}) in the brains of quinacrine-treated, RML-infected MDR^{0/0} mice. Quinacrine was given orally beginning 60 days postinoculation (dpi) for 30 days; the treated group was designated MDR^{0/0}[60–90]. The kinetics of PrP^{Sc} accumulation in the brains of untreated MDR^{0/0} and treated MDR^{0/0}[60–90] mice was analyzed quantitatively by enzyme-linked immunosorbent assay (ELISA). Error bars represent the standard error of the mean (n = 3). (Reprinted from Ghaemmaghami S, Ahn M, Lessard P, et al. Continuous quinacrine treatment results in the formation of drug-resistant prions. *PLoS Pathog* 2009;5:e1000673, with permission; copyright © 2009 Public Library of Science.)

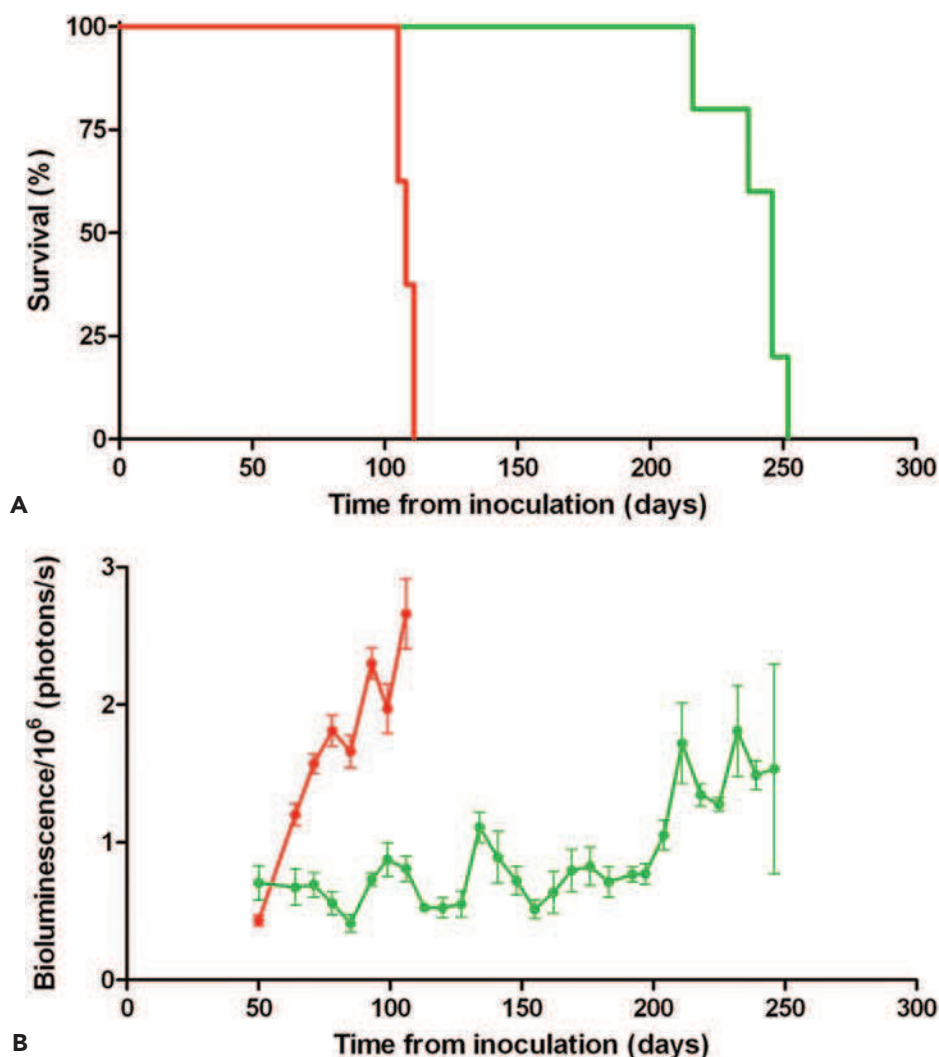

FIGURE 76.18. Bioluminescence imaging is predictive of drug efficacy. Tg(*Gfap-luc*)FVB mice were inoculated intracerebrally with RML prions; Compound B was given orally at 110 mg/kg/day in a liquid diet beginning on day 1. **A:** Kaplan-Meier survival plot and **B:** BLI signal of untreated (red) and Compound B-treated (green) mice.

GFAP is strongly upregulated in prion disease,²³⁷ we chose to use firefly luciferase (*luc*) driven by the *Gfap* promoter. Tg(*Gfap-luc*) mice⁴⁵¹ were inoculated with prions and monitored by BLI. Untreated mice develop clinical signs of prion disease at approximately 110 days post-inoculation (dpi) (Fig. 76.18), whereas the BLI signal starts to be upregulated at approximately 55 dpi (Fig. 76.18), reducing the time to disease diagnosis by approximately 50%.³⁹⁰

When we applied BLI to the assessment of compounds that extend the incubation time in mice inoculated with RML prions, we found that Compound B administration extended the survival of mice¹⁸⁹ and suppressed the bioluminescence signal. Mice were dosed continuously with Compound B starting immediately after inoculation, and the BLI signal was measured weekly. The BLI signal in untreated mice began to increase by approximately 60 dpi, whereas it remained suppressed in treated mice until shortly before the mice developed clinical signs of disease, at approximately 220 dpi (Fig. 76.18). Compound B efficacy was therefore detected by approximately 60 days, long before extension of survival could be measured by clinical observations. Equally important, BLI offers a procedure whereby multiple observations on a single animal can be obtained; this gives considerably more confi-

dence in the measurements than a single point of illness onset used in typical incubation-time studies. BLI offers a new tool in the development of therapeutics because it appears to be useful in predicting drug efficacy.

Inactivation of Prions

For many years, the scrapie agent was believed to be a slow-acting virus,³⁶³ but differences between the inactivation profiles of the scrapie agent and that of viruses provided the first clues that the agent was not a virus.^{3,5} Subsequent studies showed that as preparations from Syrian hamster brain were progressively enriched for scrapie infectivity, procedures that modified proteins were found to inactivate the samples, whereas those that modified nucleic acids had no effect.^{100,215,308,356} Protein denaturants played an important role in these studies, particularly in assessing the physical properties of prions during purification. Exposure to SDS, urea, or GdnHCl denatured PrP^{Sc}, resulting in diminished prion infectivity, susceptibility to proteolysis, and disaggregation of amyloid polymers composed of PrP 27–30.^{256,315} Prior to the studies with acidic SDS described below, sterilization of prions could be accomplished only with use of prolonged autoclaving at 134°C for 5 hours or exposure to strong alkali such as 2 N NaOH for several hours.³¹⁴

Prompted by the discovery showing that prions become protease-sensitive after exposure to branched polyamine dendrimers in weak acid,³⁸⁸ inactivation of prions by detergents such as SDS under weakly acidic conditions was investigated. SDS at pH values of less than 4.5 or greater than 10 rendered PrP^{Sc} susceptible to proteolytic digestion at room temperature.²⁸⁹ Exposure of Sc237 prions in hamster brain homogenates to 1% SDS and 0.5% acetic acid (AcOH) at room temperature reduced the prion titer by a factor of more than 10⁵.²⁸⁹ In addition to investigations of Sc237 prions, sCJD prions in human brain homogenates and bound to steel wires were studied; these prions harbored Met at codon 129 and a 21-kD protease-resistant fragment (designated type MM1). Infectivity bound to the wires was bioassayed by implanting the wires into the brains⁴⁵² of mice expressing a human–mouse chimeric transgene.²⁰⁴ sCJD prions in brain homogenates were more than approximately 10⁵-fold more resistant to inactivation than Sc237 prions in brain homogenates. Inactivation of sCJD(MM1) prions bound to wires was achieved by exposure to 1% SDS and 0.5% AcOH for 15 minutes at 121°C.²⁸⁹ Whether acidic SDS might form the basis for a noncorrosive disinfectant that is suitable for sterilization of surgical instruments and some invasive diagnostic devices remains to be determined.¹³³ Other approaches to inactivation of prions that might contaminate surgical, medical, dental, and ophthalmologic equipment include proprietary phenolic and alkaline cleaning solutions, as well as enzymatic cocktails.^{108,173,317}

CONCLUSIONS

Much of prion biology is unprecedented. As such, it is not surprising that some aspects of this emerging field have been embraced rather slowly. Although prion replication resembles viral replication superficially, the underlying principles are quite different. For example, in prion replication, the substrate is a host-encoded protein, PrP^C, that undergoes a conformational change to form PrP^{Sc}. In contrast, viruses harbor a DNA or RNA genome that directs the synthesis of most, if not all, of the viral proteins. Viral replication requires faithful copying of the viral genome followed by assembly of mature virions, each of which contains of a nucleic acid genome surrounded by a protein coat. In contrast, prions seem to be composed solely of PrP^{Sc} trimers.

When viruses pass from one species to another, they often replicate without any structural modification, whereas prions undergo a profound change. The prion adopts a new PrP sequence, which is encoded by the chromosomal PrP gene of the host. Changes in the PrP amino acid sequence can result in a restriction of transmission for some species while making the new prion permissive for others. In viruses, different properties exhibited by distinct strains are encoded in the viral genome, whereas in prions, strain-specific properties are enciphered in the conformation of PrP^{Sc}.

Whereas viral diseases are infectious illnesses caused by a foreign infectious agent, prion diseases may manifest as inherited or sporadic disorders as well as infectious maladies. The inherited and sporadic forms are caused by the spontaneous, endogenous generation of prions, whereas the infectious prion diseases are caused by exposure to exogenous prions.

Whether PrP^{Sc} in mammals represents a misfolded protein or an alternatively folded protein, as with yeast prions,

remains to be established. The concept that PrP^{Sc} might be an alternatively folded protein is appealing in some respects but puzzling in others. If PrP^{Sc} is an alternatively folded protein with some as-yet undefined function, then all mammals seem likely to be capable of producing small amounts of this isoform. Sufficiently low levels of PrP^{Sc} would prevent extracts prepared from uninoculated controls from causing disease in inoculated recipients after prolonged incubation times. Having considered such a scenario, we must next inquire about how distinct conformations of PrP^{Sc} encipher the properties of different prion strains.¹²⁹ How such conformational variations might affect the “normal function” of PrP^{Sc} is unknown.

Wider Spectrum of Neurodegenerative Diseases Caused by Prions

Over the last three decades, there has been a steady accumulation of evidence that each neurodegenerative disease is caused by a particular protein.^{310,311} As with the prion diseases caused by PrP^{Sc}, amyloid deposits in other neurodegenerative diseases were found to have the same protein as that identified by molecular genetic studies. For example, the amyloid fibrils in Alzheimer's disease (AD) were found to contain the A β peptide^{137,241} that is cut from the larger amyloid precursor protein (APP); familial AD was shown to be caused by mutations in APP.¹³⁸ Subsequently, Tg mice expressing mutant human APP were found to have amyloid plaques composed of the A β peptide.^{122,165} Those Tg mice expressing APP with the Swedish mutation were found to exhibit accelerated accumulation of amyloid plaques and astrocytic gliosis after inoculation with brain homogenates from old Tg mice expressing the Swedish mutation (Table 76.9).^{150,252,416} Recently, it was reported that Tg mice expressing wt human APP developed A β plaques after inoculation with homogenates prepared from the brains of human AD patients.²⁶³

In AD, neurofibrillary tangles (NFTs), which are composed of the tau protein, are abundant within neurons.^{38,148,207,219,438} Both the A β amyloid plaques and the NFTs begin in the entorhinal cortex and spread both rostrally and caudally.^{34,35} These findings suggest that A β prions move from one neuron to another as A β accumulates in the extracellular space to form plaques. Many experimental findings argue that oligomers of A β stimulate neurons to induce a structural transition in tau that leads to its aggregation and subsequent deposition in NFTs.²¹¹ Notably, A β dimers isolated from the cortex of AD patients induced tau hyperphosphorylation and neuritic degeneration in cultured cells.¹⁷⁹

The secondary but important role of NFTs in the pathogenesis of AD was resolved when mutations in the tau gene were found to cause heritable tauopathies including familial frontotemporal dementia (FTD), inherited progressive supranuclear palsy (PSP), and Pick's disease,¹⁶⁹ but not familial AD. Aggregates formed of truncated recombinant tau were shown to enter cells and seed the polymerization of endogenous tau.^{116,149} Self-propagating tau aggregates not only pass from cell to cell in culture but also in the brains of Tg mice.^{75,389} It seems plausible that aggregates are released into the extracellular space after a cell dies; the aggregates then break apart and infect other cells. The formation of tau prions is likely to be the central event in the tauopathies including the sporadic and familial FTDs, PSP, Pick's disease, and chronic traumatic encephalopathy (CTE).

TABLE 76.9 Neurodegenerative Diseases Caused by Prions. For Each of these Disorders, There Is Good Evidence in Animals and/or Cultured Cells for a Particular Protein Adopting an Alternative Conformation, Which Becomes Self-Propagating

Prion diseases	Precursor proteins	Prion forms	Protein deposits	Self-propagation in mammals	Self-propagation in cells
CJD/scrapie	PrP ^C	PrP ^{Sc}	PrP plaque	inoc wt & Tg mice	N2a, GT1
Alzheimer's	APP	A β	A β plaque	inoc Tg(Δ APP) mice	
Tauopathies (FTD, PSP, Pick's, CTE)	tau	tau aggregates	NFT, Pick bodies	inoc Tg(HuTau), inoc Tg(HuTau,P301S) & inducible Tg(HuTau, Δ K280) mice	C17.2, HEK293
Parkinson's	α -synuclein	SNCA aggregates	Lewy body	inoc Tg(HuSNCA,H53T) mice & Lewy bodies in fetal human grafts	
ALS	Δ SOD1	Δ SOD1 aggregates	Bunina body		N2a
Huntington's	Δ Htt	Δ Htt aggregates	Nuclear inclusion		Cos7

Studies of athletes participating in contact sports have shown that some individuals develop FTD after repeated traumatic brain injury (TBI).⁸⁴ In boxers, this illness has been called punch-drunk dementia as well as dementia pugilistica,⁸³ but in football players, a similar progressive neuropsychiatric disorder, in which numerous NFTs accumulate in the frontal lobes, is commonly referred to as CTE.^{245,277} Thousands of soldiers who served in the Iraq and/or Afghanistan wars have had posttraumatic stress disorder (PTSD) with neuropsychiatric symptoms indistinguishable from those found in FTD and CTE. A recent report of a 27-year-old male Marine with PTSD, who committed suicide, argues that concussions from shock waves from roadside bombs (improvised explosive devices) can initiate a tau prion-mediated process indistinguishable from football players with CTE.²⁷⁶

Recent findings implicate a prion-like spread of misfolded α -synuclein in Parkinson's disease.^{9,264,275} In Parkinson's disease, the aggregated forms of α -synuclein are thought to begin to accumulate in the peripheral nerves that innervate the gut and spread rostrally via retrograde axonal transport to the substantia nigra where they are toxic to dopamine neurons.³⁶ With α -synuclein (SNCA), a protein whose overexpression and misfolding causes Parkinson's disease,^{299,366} studies with Tg mice expressing mutant HuSNCA(A53T) showed marked acceleration of disease after inoculation with brain extracts from older Tg(HuSNCA,A53T)83 mice.^{132,264} The uninoculated Tg83 mice developed neurologic dysfunction at approximately 435 days of age, whereas those inoculated intracerebrally with 20 μ l of a brain homogenate prepared from a 2-month-old Tg83 mouse exhibited CNS dysfunction at approximately 359 days of age. When Tg83 mice were inoculated with homogenates of the brains of two 18-month-old Tg83 mice containing insoluble aggregates of phosphorylated mutant α -synuclein, the mice showed abbreviated median survival times of 182 days and 193 days. These results support the hypothesis that α -synuclein prions mediate the pathologic deposition of synuclein aggregates, which is accelerated by inocula prepared from brains of old Tg83 mice that contained diffuse perikaryal inclusions of mutant α -synuclein.

In cell culture, the formation of fibrils of rec α -synuclein was required for the protein to enter the cell. These fibrils were

internalized via endocytosis, whereas monomers diffused passively across the membrane.²¹⁶ Endocytosis of α -synuclein aggregates resulted in cell death³⁸³ and the release of toxic aggregates into the extracellular space where they infected other cells. Like tau, α -synuclein has also been shown to pass from cell to cell in both culture and the brain.⁹⁵

Aggregates composed of mutant SOD1(H46R) causing familial amyotrophic lateral sclerosis (ALS) were able to cross into N2a cells by macropinocytosis where they nucleated aggregation of cytosolic, mutant SOD1 protein.²⁶⁶ Once initiated, mutant SOD1 aggregation was found to be self-perpetuating. Transfer of mutant SOD1 aggregates from cell to cell did not require contacts between cells but depended on the extracellular release of the aggregates. These findings contend that SOD1 aggregates are prions and the aggregation is a self-propagating process. In addition to mutant SOD, mutations in two RNA-binding proteins, TDP-43 and FUS, have been identified in patients with familial ALS. As well as being involved in numerous events related to RNA metabolism, each form aggregates in neurons in ALS and FTD.⁴⁰⁸ Recent evidence also indicates that both TDP-43 and FUS contain prion-related domains rich in glutamine and asparagine residues, and in the case of TDP-43, this domain contains a substantial number of disease-causing mutations.^{117,181}

The prion-like spread of protein aggregates has been demonstrated for polyglutamine peptides,³²⁰ which represent a key sequence motif in the huntingtin protein. Additional polyglutamine expansions in the huntingtin protein cause Huntington's disease, with the number of repeats generally related to the age of onset. Aggregates of chemically synthesized polyglutamine peptides killed cultured cells after endocytosis and transport into the nucleus.⁴⁵⁰ Following uptake, aggregates initiate conformational conversion of endogenous polyglutamine-containing proteins, resulting in persistent protein misfolding.^{44,407}

The ability to model disease states using synthetic peptides and recombinant proteins refolded into pathogenic conformations has enlarged the spectrum of prion diseases and opened new avenues of investigation into the molecular mechanisms of degenerative diseases. For example, systemic amyloidosis caused by serum amyloid A (SAA) may be transmitted by a

prion-like mechanism, and amyloid fibers composed of synthetic peptides corresponding to fragments of the SAA protein were found to accelerate the disease process.^{57,180,368,424,439,440}

In summary, the field of prion biology still seems to be in its infancy. Although the number of prions identified in mammals (now at more than half a dozen) and in fungi (now more than 10) will undoubtedly continue to expand, we have no idea about prions in all the other phylogeny.^{44,78,88,424} Numerous attempts to identify auxiliary molecules that participate in the replication of mammalian prions have been unrewarding, to date. There seems to be little support for the outdated notion that a viral-like nucleic acid, which encodes for and directs the synthesis of progeny prions, will someday be found.⁷⁸

Defining a physiologic role for mammalian PrP prions has eluded investigators, but the MAVS prion seems to be required for innate immunity to RNA virus infection and the CPEB prion appears to modulate long-term memory in the invertebrate *Aplysia*. Studies of yeast prions have delineated plausible functions for several of these proteins, whereas investigations of the [HET-s] prion have defined its complex functions in preventing heterokaryon incompatibility in *Podospora anserina*.

The mammalian prions composed of PrP, A β , tau, α -synuclein, SOD1, and huntingtin all cause distinct neurodegenerative diseases. In each of these disorders, the mammalian prion proteins adopt a β -sheet-rich conformation and readily oligomerize. The oligomeric states of mammalian prions are thought to be the toxic forms, and assembly into larger polymers such as amyloid fibrils seems to be a mechanism for minimizing toxicity. To date, there is not a single medication that halts or even slows a neurodegenerative disease caused by prions. This dilemma may be a bellwether of the unique pathogenic mechanisms that feature in each of the prion diseases and of the urgent need to develop informative molecular diagnostics and effective antiprion therapeutics.

- Alphaviruses (*continued*)
 nucleocapsid core assembly, glycoprotein synthesis, and processing in, 631f, 642–643, 642f
 replicon systems in, 644–645
 translation and viral-encoded replication proteins in, 637–640, 638f, 638t, 639f
 virion budding in, 643, 644f
 salmonid, 681–682
 Semliki Forest, 680–681
 Southern elephant seal, 681
 structure of, virion
 icosahedral symmetry in, 72
 in immature virion, 631
 internal, 72, 73f
 in mature virion, 630–631, 630f
 molecular organization in, 72, 73f
 structural proteins in, 631–633, 631f, 632f
 surface envelope proteins in, 73, 73f
 uncoating program triggering in, 97
 Alphaviruslike supergroup, 111
 Alphavirus vectors, for vaccine delivery, 403
 AL-RNA, 1835
 Altered (A) particles, in picornaviruses, 466
 Alum, 405
 Alzheimer's disease, neurofibrillary tangles and prions in, 2450, 2451t
 Amantadine, 342f, 345–346, 346f, 1178, 1178f
 development of, 8
 for influenza viruses, 1232–1233
 on viral replication, 342f
 virus targeting of, 40
 Ambisense genomes, 110
 Ambisense RNA viruses, expression and replication in, 119–121, 120f
 Amdoviruses, 1769, 1769t. *See also* *Parvoviridae* (parvoviruses)
 Amoebae, giant viruses with mosaic gene repertoires from, 2281–2283, 2282f
 Amplicon, 423
 Amplification, gene, in tumor cells, 169
 Amprenavir, 359f
Amsacta moorei virus (AMV), lateral gene transfer in, 309
 Amyloid
 in HET-s protein prion, 2375–2377, 2377f
 in PrP
 in Creutzfeldt-Jakob disease, 2421
 definition of, 2420t
 in PrP 27-30
 PrP amyloid in, 2420t, 2421
 x-ray fiber diffraction of, 2429, 2431f, 2432f
 in Ure2p, as [URE3], 2373–2374, 2374f
 in yeast prion, variant propagation and, 2376, 2377f
 Amyloidosis
 systemic, prions in, 2451–2452, 2451t
 transmissible
 of SUP35P, 2374t, 2375
 of URE2P, 2372–2375 (*See also* [URE3])
 Amyotrophic lateral sclerosis (ALS)
 enteroviruses in, 512
 familial, neurofibrillary tangles and prions in, 2451, 2451t
 Anal cancer
 in HIV-positive male homosexuals, 1690
 human papillomavirus in, 1690
 Analyte-specific reagent (ASR), 430
 Anchorage independence, 29, 155
 Ancient viruses, 287, 288f, 289–290, 291f
 Anderson, Tom, 4
 Anelloviruses, 444–445
 Angioimmunoblastic T-cell lymphoma, with Epstein-Barr virus, 1946
 Animal models. *See also specific viruses*

- F (fusion) protein/glycoprotein
 in alphaviruses, 79
 class I, 76f–78f, 77–78
 class II, 62f, 77f, 78–79, 79f
 class III, 79–80, 80f
 conformational rearrangements in, 75–77
 in herpesviruses, 80
 in human metapneumovirus, 1089f, 1090f, 1092
 in human respiratory syncytial virus, 1088f–1090f, 1091–1092
 in measles virus, 1044f, 1046–1047, 1046f, 1047f
 in membrane fusion, models of, 978
 in mumps virus, 1026t, 1027
 in parainfluenza viruses, 1004–1005, 1004f, 1005t
 in paramyxoviruses, 78, 78f, 973–979, 979t
 atomic structures of, 973f, 975–976, 975f, 976f
 class I, 974
 helical hairpin and, 974–975, 974f
 general properties and structure of, 969f, 973–974, 973f, 977f
 membrane fusion mediated by
 cleavage activation in, 978, 979t
 HN activation of F protein for, 977–978
 mechanism of, 976–977, 977f
 postfusion structure of, 974f, 975–976, 975f
 prefusion structure of, 973f, 975–976, 975f
 refolding of, 976, 976f
 Frameshift mutations, 39
 Frameworks, 60f, 61f, 62–63, 63f, 64f
 Frequency, possible increased, 327–328, 328f
 Freund's adjuvant, 404–405
 Frontotemporal dementia (FTD),
 neurofibrillary tangles and prions
 in, 2450–2451, 2451t
 Frosch, 3
 Fulcrum, 58, 59f
 Full-site integration, 1526
 Fulminant hepatitis, 569–570
 Functional assay, 435
 Fungal prions, 2432f, 2445
 Furin, 979
 Furosemide, for adenoviruses, 1754
 Fusion
 back-fusion, in rhabdoviruses, 896, 897f
 bilayer, 75, 75f
 membrane, glycoproteins in, 95–96, 95f
 membrane, in entry, 75–80, 95–96, 95f
 bilayer fusion in, 75, 75f
 class I fusion proteins in, 76f–78f, 77–78
 class II fusion proteins in, 62f, 77f, 78–79, 79f
 class III fusion proteins in, 79–80, 80f
 conformational rearrangements in fusion
 proteins in, 75–77
 flavivirus envelope subunit (E) in, 62f, 77f, 78–79, 79f
 influenza virus hemagglutinin in, 76f, 77
 penetration by, 95–96, 95f
 VSV-G in, 79–80, 80f
 Fusion inhibitors, in human
 immunodeficiency virus,
 342f–344f, 345
 Fusion loop, 79, 79f
 Fusion peptide, 76f, 77, 96
 in retrovirus transmembrane subunit TM,
 1459
 in rhabdoviruses, 896, 897
 Fusion pore, 75, 75f, 76f
